Several factors are responsible for the increased susceptibility of the facial nerve to injury during multiple operations on the parotid gland. Ischaemic anoxia of the nerve as a result of surgical interference with the vasa nervorum is quoted (Patey and Moffat, 1961). In fact, these authors, using the experimental model of the rabbit, found that by direct blunt trauma of the facial nerve it was difficult to produce paralysis. The mechanism of ischaemia applies to primary surgery but more obviously to secondary surgery when the facial nerve is stripped of the few blood vessels that may remain in the adherent scar tissue resulting from previous interference. In this same situation it becomes more difficult to recognize and to trace the branches of the facial nerve, thereby resulting in inadvertent direct trauma. After recurrence of either a malignant tumour or a pleomorphic adenoma the clearance required to reduce the likelihood of a further recurrence often implies deliberate sacrifice of a branch of the facial nerve. Furthermore, in the presence of scar tissue from previous surgery it may be easy to confuse recurrence with fibrosis.

Accurate diagnosis of a parotid tumour on clinical assessment alone is notoriously difficult unless there is obvious evidence of its malignant nature such as invasion of neighbouring structures, facial palsy or metastases, yet even a benign tumour can lead to a facial palsy (Wilkie and White, 1969). Those who have the special experience required of fine needle biopsy can plan treatment according to the preoperative diagnosis (Eneroth, 1964; Eneroth and Zajiceck, 1965). Indeed, aspiration biopsy by fine needle is regarded as an essential preliminary to surgical treatment (Webb, 1974). Others (Janes, 1957; Patey and Thackray, 1958) consider that previous knowledge of the nature of the tumour would not influence their surgical treatment and that cell spillage and implantation is too great a risk. From the relatively low incidence of injury of the facial nerve (6·5 per cent) during primary extended surgery of both benign and malignant tumours (*Tables IV, V*) it would seem justifiable to treat all lesions of the parotid gland by conservative formal parotidectomy unless clinically they are obviously malignant. If during this operation it is apparent on the evidence of frozen section or from the appearance of the tumour that it is malignant the surgical procedure should be adjusted accordingly. However, it is emphasized in the light of these findings that every exploratory procedure of the parotid gland should be a conservative formal parotidectomy, not only to cure 85 per cent of all patients with parotid tumours (Patey, 1966) but also to avoid the much greater chance of injuring the facial nerve during secondary surgery.

Recognition of infection associated with intravenous catheters

R. FREEMAN AND B. KING*

SUMMARY

Four cases are described in which the patients suffered from bacteriaemia due to infected intravenous infusions. Although all the patients were pyrexial, the white cell count was normal in all 4 cases at diagnosis and the infusion site appeared innocent.

Following removal of the intravenous catheter and the institution of antibiotic therapy in each case, neutrophilia and localizing signs developed. It is stressed that a normal white cell count and an innocent appearance at the infusion site do not exclude this complication of intravenous therapy. Possible reasons for this presentation of sepsis are discussed.

INFECTIVE complications of indwelling intravenous catheters have recently been recognized as a potential hazard in any patient requiring prolonged intravenous therapy (Freeman and King, 1972; Cox, 1973). This is particularly so in patients receiving parenteral nutrition—so called 'intravenous feeding' (Ashcraft and Leape, 1970; Curry and Quie, 1971). We describe the following cases to emphasize one way in which infective complications may present.

Case reports

Case 1: A 33-year-old woman who underwent laparotomy for intestinal obstruction developed paralytic ileus postoperatively. She required prolonged intravenous therapy, and on the third day of this régime her general condition deteriorated. The main features of her illness were fever, tachycardia and a feeling of general malaise, associated with some nausea. The intravenous fluids being given were simple electrolytes (normal saline, dextrose-saline and 5 per cent dextrose solutions). She did not receive any hypertonic amino-acid or lipid preparations. The illness continued for 48 hours, during which time the white cell count remained normal and the infusion site appeared unremarkable, apart from mild hyperaemia. Blood cultures were taken and the patient was given parenteral gentamicin (80 mg 8-hourly). Only marginal improvement occurred over the next 24 hours, but a rapid resolution followed the removal of the intravenous catheter. Within 3–4 hours the temperature had fallen to normal levels and the tachycardia abated overnight. The patient admitted to feeling much better.

Over the next 3 days the white cell count rose, and a neutrophil leucocytosis developed. Five days after the removal of the intravenous catheter a large abscess had appeared at the infusion site, and this was evacuated. Culture of the contents revealed *Staphylococcus aureus*, and this organism was also subsequently reported to be present in the blood cultures. Antibiotics were continued for a further period to minimize the risk of endocarditis.

Case 2: A man aged 45 years suffered multiple injuries in a road traffic accident and required parenteral nutrition. In the second week of this therapy he developed a hectic fever with no obvious source of infection. A chest X-ray, urine examination and the white cell count were all unhelpful. In particular, the white cell count was found to be normal, with a normal differential count. One of the infusion sites showed slight erythema. Blood cultures were taken and the catheter was removed, the severed tip being sent for culture. Both the blood cultures and the catheter tip culture yielded *Staph. aureus*, and the patient was immediately given cloxacillin at a dose of 500 mg intramuscularly 6-hourly. The temperature rapidly settled and this was associated with a rise in the white cell count and the development of a neutrophil leucocytosis. The site of the infusion developed into a large abscess requiring drainage whilst he was being treated for his septicaemia. The evacuated pus was sterile on culture.

Unfortunately, the patient eventually died as a result of renal failure which had complicated his other injuries.

Case 3: A 55-year-old man was receiving parenteral nutrition with amino-acid solutions and lipid suspensions whilst recovering from major abdominal surgery for ulcerative colitis, complicated by paralytic ileus. On the fifth day of this régime he became febrile and unwell. No source of sepsis was found and the white cell count remained normal. The infusion site was slightly erythematous and there was some thrombosis of the vein. Blood cultures yielded *Staph. aureus*, and treatment with lincomycin 500 mg intramuscularly 6-hourly and cloxacillin 500 mg intramuscularly 6-hourly was given. There was little improvement over the following 3 days, during which time he was noted to have several rigors, but a rapid fall in temperature and a gradual improvement in his general condition occurred after removal of the intravenous catheter. Culture of the catheter tip was negative, but the infusion site developed into an abscess shortly afterwards and culture of the pus obtained from this lesion produced a scanty growth of *Staph. aureus*. Following the removal of the catheter the white cell count revealed a neutrophil leucocytosis.

Case 4: A man aged 30 years was admitted following a road traffic accident, having sustained multiple injuries. Prolonged intravenous feeding was given, but after 6 days the patient began to show a low grade pyrexia which persisted. Careful inspection of the infusion sites revealed no abnormality and the white cell count was normal. The white cell count had been slightly elevated at admission but had returned to normal within 3 days. The catheter tip was removed for culture and this produced a heavy growth of *Staph. albus* (coagulase negative), but owing to doubts about its significance no specific therapy was given until blood cultures revealed the same organism. Therapy with cloxacillin 500 mg intramuscularly 6-hourly was commenced although the patient was by that time afebrile. Over the 2 days following removal of the catheter the white cell count developed a neutrophil leucocytosis, and the infusion site developed cellulitis, but this resolved without suppuration.

Discussion

These 4 cases illustrate a presentation of sepsis following intravenous infusions which is characteristic once recognized, but which is easily overlooked. A summary of the details of the cases is given in *Tables I* and *II*. The important features are:

1. The infusion site may look quite innocent, exhibiting only a slight erythema over the vein, and certainly not showing any sign that it is the source of a septicaemia.

2. The white cell count is characteristically normal, in both total count and differential count. This may

not only lead the investigation away from the infusion site, but may even give the impression that the patient's illness is not even infective.

3. Following the recognition of the complication, effective therapy consists of both chemotherapy and removal of the catheter. *Cases* 1 and 3 suggest that chemotherapy alone may not succeed until the foreign material is removed.

4. The catheter having been removed and chemotherapy having been started, the white cell count rises and a neutrophil leucocytosis develops. Suppuration or cellulitis follows at the infusion site.

All these cases have one other feature in common: the infusion was administered in each case via an indwelling intravenous catheter. Previous work has shown that such catheters frequently yield an organism when the tip is cultured, and that this is more likely to occur when the catheter has been *in situ* for more than 2 days (Freeman and King, 1972). The route by which the organisms gain access is still uncertain, but the fact that indwelling intravenous catheters become infected is now well recognized. What is notable about the patients described here is their apparent lack of host response, both locally at the infusion site and generally as expressed by the white cell count. Three factors may be concerned. First, the nature of the infective lesion is similar to that found in infective endocarditis. Thus, there is an infected focus in the major bloodstream which the body is unable to supply with inflammatory cells since there is no blood supply to the lesion. It is noteworthy that a normal white cell count is often found in endocarditis (Weinstein and Rubin, 1973). Secondly, indwelling intravenous catheters are yet another example of foreign material implanted in the body. Indeed, they are probably the commonest instance of this. There is thus a parallel with infections of other prosthetic implants. It is characteristic of the infections complicating Spitz–Holter valves in hydrocephalic children that there is a lack of inflammatory response in the cerebrospinal fluid despite the easy isolation of bacteria (Cohen and Callaghan, 1961). These infections often require the removal of the foreign material to control them.

Thirdly, recent work has suggested that in patients receiving prolonged parenteral nutrition, depletion of body phosphate may occur, leading to a diminished chemotaxis and bactericidal power in the neutrophils (Craddock et al., 1974). Thus, the host resistance may be diminished in these patients. However, one of our cases received only crystalloid, and in all the cases recovery occurred without phosphate repletion. Since phosphate studies and neutrophil function tests were not carried out on our patients we are unable to prove that these abnormalities were not present, but this last factor is unlikely in these cases in view of the response to treatment and the very rapid local and general inflammatory reaction which ensued.

Finally, it should be stressed that in a patient receiving prolonged intravenous therapy, infection arising from the infusion site should always be considered as a likely cause of an unexplained pyrexia. If the white cell count is normal, infection of this site is probably more likely than infection elsewhere. The infection rate can be reduced by early removal of the catheter or by rotation of sites (Freeman et al., 1973), and the infected catheter may be detected by serial nitroblue tetrazolium (NBT) tests (Freeman and King, 1972; Freeman et al., 1973).

Pilonidal sinus treated by phenol injection

B. A. SHOREY*

SUMMARY
The method of using phenol injections for the treatment of pilonidal sinus is described in detail. This is a simple, safe and painless method which may be used as a day case procedure. The results are discussed and compare very favourably with the more radical forms of treatment.

THE first reported case of a pilonidal sinus that was successfully treated was described by Anderson (1847). The sinus was incised and the enclosed hair removed. Since that time many papers have appeared on the aetiology and treatment of this condition.

It was originally thought that the aetiology was congenital due either to remnants of neural canal becoming separated or to ectodermal inclusions (Mallory, 1892; Kooistra, 1942). However, since the papers of King (1946), showing that the hairs present in these sinuses have their roots nearest the opening, and of Patey and Scarff (1946), describing pilonidal sinus in the interdigital clefts of barbers, the acquired theory of aetiology has become generally accepted. Brearley (1955) and Raffman (1959) also contributed papers supporting the acquired theory and suggesting ways in which the hairs enter the skin.

Pilonidal sinuses have now been reported in many areas of the body—perineum (Smith, 1948), umbilicus (Steck and Helwig, 1965), interdigital cleft (Currie et al., 1953), scalp (Stevens and Anderson, 1961), amputation stump (Shoesmith, 1953), axilla (Aird, 1952). It would thus seem impractical to think of this condition as congenital.

Method

The method used for phenol injection is similar to that first described by Maurice and Greenwood (1964). Following general anaesthesia with endotracheal intubation, the patient is placed prone on the operating table. The table is then raised in the centre or the patient lifted on to pillows to obtain the 'jack-knife' position. The patient, having previously been shaved from the waist to mid-thigh posteriorly, has the buttocks held apart by the use of 7·5-cm strapping, thus exposing the natal area and anal verge. At this stage further shaving may be necessary, especially deep in the natal cleft. The area is now prepared and towelled up in the normal manner. A swab or large piece of cotton wool is used to protect the anus, while the rest of the area is liberally coated with paraffin jelly (Vaseline) to protect it from the phenol.

After careful probing any loose hairs are removed with forceps from the sinus and any of its side tracts. With a blunt needle which fits snugly into the sinus orifice and a 10-ml syringe, the sinus is injected with a solution of 80 per cent phenol. No excess pressure is used for fear of the phenol being forced into the surrounding tissue lining the sinus and causing a local inflammatory reaction.

It has been suggested (Stephens and Sloane, 1969) that the operator should wear glasses as protection against any splash of phenol. This problem did not arise in the present series. On commencing the injection, phenol can be seen issuing from the side canals. The phenol is left *in situ* for 2 minutes and then expressed by pressure. The excess is mopped away with the debris. This manœuvre is repeated two or three times; the orifice of the sinus is seen to blanch at this stage.

A dressing of paraffin jelly is applied, the excess Vaseline being removed. The patient is allowed home when he has recovered from the anaesthetic.

Results

In the Bristol Royal Infirmary during the period 1968–72, 253 patients with pilonidal sinus came to surgery. Various forms of treatment were undertaken as shown in *Table I*.

Table I: METHODS OF TREATMENT OF PILONIDAL SINUSES

	Laying open	Primary suture	Brush technique	Phenol injection
No. of patients	179	42	9	23
No. of failures or recurrences	14	7	2	2

Although those treated by phenol injection comprise only a small percentage of the total, it can be seen that the results compare favourably with those of other methods.

Of the 23 patients so far treated, 20 were male and 3 female; their ages ranged from 18 to 59 years. The presenting symptoms were recurrent abscess formation or a persistent discharge; most of the patients had been having symptoms for over a year.

Successful treatment was judged by epithelization occurring without any discharge or pain; 21 cases were deemed a success while 2 were failures. Of the 2 failures, one was at first successful but recurrence occurred after 9 months with a further abscess. The other case proved very difficult and was resistant to any form of treatment. Phenol injections failed twice and he subsequently had 6 other operations. It was emphasized to all the patients that postoperatively the natal cleft must be kept free of hair by shaving. Personal hygiene of the area was also encouraged.

---

* Department of Surgery, Bristol Royal Infirmary.

Discussion

A large number of operations have been described for the treatment of pilonidal sinuses and all have their supporters. Some of the procedures that have been described for this relatively minor condition are major undertakings, and it is not surprising that Walters and MacDonald (1958) suggested a return to simple treatment. Phenol injection is a simple procedure and offers many advantages to the patient. The length of hospitalization is minimal; all the patients in this series were discharged on the day following operation. It would therefore be a logical step to treat all pilonidal sinuses as day cases, for there is little danger after recovery from the anaesthetic. In fact, 4 patients treated by Stephens and Sloane (1969) had phenol injections as outpatients without a general anaesthetic.

Following phenol injection patients have very little discomfort and are thus able to return to a normal routine almost immediately. Other simple forms of treatment such as marsupialization are widely practised but healing is prolonged; an average of 86 days was quoted by Berkowitz (1949). This leads to discomfort, excess hospitalization, frequent dressings, prolonged medical supervision and more time off work.

Primary excision and closure has many advocates (Holman, 1946; Mandel and Thomas, 1972; Casten et al., 1973), and in good hands very satisfying results are obtained, but failures occur (Rogers and Hall, 1935), hospitalization is longer and postoperative discomfort more severe than with phenol injections. The most drastic operation of rotational flaps has not been popular owing to the length of stay in hospital and postoperative pain. However, good results have been obtained (Davis and Starr, 1945).

The simpler methods of treatment, such as diathermy coagulation (Jacobsen, 1959; Flannery and Kidd, 1967) and incision and brush technique (Lord and Millar, 1965), have the disadvantage that in each technique an incision is made over the sinus. This means that postoperatively the wound has to be dressed and frequent medical supervision is required. However, phenol injection (Maurice and Greenwood, 1964; Stephens and Sloane, 1968; Stewart and Bell, 1969) has several advantages. The operation is simple and the only postoperative dressing required is small, its purpose being to prevent any excess phenol being expressed on to the skin.

Acknowledgement

I would like to thank Mr H. K. Bourns for allowing me to study the patients under his care and for his encouragement in writing this paper.

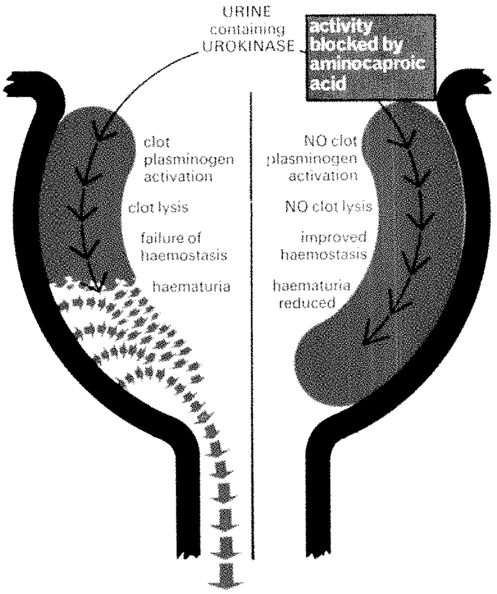
The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

The surgical management of ingrowing toenail

W. R. MURRAY AND B. S. BEDI*

SUMMARY

A retrospective review has been carried out on 200 randomly selected patients with ingrowing toenail in order to assess the surgical management and its results. There was a predominance of males between the ages of 11 and 30 with an ingrowing toenail. Despite the high recurrence rate following simple avulsion of the toenail, its place in the initial management of the condition is justified. As regards more definitive surgery, total proximal nail bed ablation was found to give the best results. Sepsis at the time of operation neither increased the recurrence rate nor caused severe postoperative sepsis.

A surgical management policy for the treatment of ingrowing toenail is outlined and discussed.

AN ingrowing toenail complicated by pain and sepsis is a common condition often treated by chiropodists, general practitioners and casualty surgeons before being referred for a definitive treatment. The surgical treatment of this condition and the decision as to which form of treatment should be instituted are commonly left to relatively inexperienced junior surgical staff, who would welcome a clear-cut management policy. Unfortunately, this does not appear to exist for ingrowing toenails.

Lloyd-Davies and Brill (1963) showed that conservative outpatient management gave good results. However, their policy requires a careful and time-consuming follow-up by both the medical and nursing staff, combined with a high degree of patient co-operation.

The aims of the present study were therefore first to review the management and success of treatment of patients with a diagnosis of ingrowing toenail seen at the Western Infirmary, Glasgow, and secondly to construct a workable management policy, which could be applied to all such cases in the future.

Patients

The case records of 200 patients with ingrowing toenails between 1966 and 1970 were randomly selected and reviewed retrospectively. Patients with a diagnosis of onychogryphosis were excluded from the survey.

The surgical procedures used and reviewed in this survey were as follows:

1. Simple avulsion of the toenail.
2. Wedge resection of the medial or lateral aspects of the proximal nail bed as described by Winograd (1929).
3. Wedge resection of both medial and lateral aspects of the proximal nail bed by the technique of Winograd (1929).
4. Total proximal nail bed ablation as described by Zadik (1950).

Results

Epidemiology

The survey showed that the condition of ingrowing toenail affects males (68·5 per cent) more commonly than females (31·5 per cent). Males in the second and third decades of life accounted for 56 per cent of the patients in this series, the male predominance continuing into the fourth decade after which the incidence of ingrowing toenail is similar for both sexes (*Fig.* 1). Of the 200 patients in this study, 143 patients had only one hallux affected, and in 138 patients the condition involved both lateral and medial nail folds concurrently. In the remaining 62 cases where only one nail fold was affected at presentation it was more commonly the lateral fold than the medial fold (*Table I*).

Table I: DETAILS OF PATIENTS WITH INGROWING TOENAILS

	Patients	
Site of disease	No.	%
Single hallux	143	71·5
Both halluces	57	28·5
Both nail folds	138	69·0
Lateral fold only	43	21·5
Medial fold only	19	9·5

Table II: RESULTS OF SIMPLE AVULSION OF THE TOENAIL AT THE SAME SITE

No. of avulsions at the same site	Patients		Recurrence rate (%)
	No.	%	
1	95	65·5	64
2	35	24·1	86
3	15	10·4	80

Simple avulsion

One hundred and forty-five patients (72·5 per cent) had been submitted to at least one simple avulsion of the toenail, 70 per cent of these procedures being performed under a local anaesthetic and 30 per cent under a general anaesthetic. *Table II* shows that 65·5 per cent of the patients who had avulsion of the toenail had only one avulsion, 24·1 per cent had two avulsions at the same site and 10·4 per cent had more than two avulsions at the same site.

The recurrence rates of ingrowing toenails requiring further surgery in this group were 64 per cent following the first avulsion, 86 per cent following the second avulsion and 80 per cent after more than two avulsions.

---

* Department of Surgery, Western Infirmary, Glasgow.

Nail bed ablation

One hundred and fifty-eight patients (79 per cent) in this series sooner or later had some form of nail bed ablation, 65 per cent of these having had a previous simple avulsion. Ninety-seven per cent of the nail bed ablation procedures were performed under a general anaesthetic and 3 per cent under a local anaesthetic.

Table III shows that the commonest operation used was total proximal nail bed ablation (60 per cent), with 35 per cent undergoing Winograd single wedge resection and 5 per cent having a Winograd double wedge resection. The recurrence rate or nail regrowth rate at the site of ablation was similar for total proximal nail bed ablation and single Winograd wedge resection at 27 per cent, but higher for Winograd double wedge resection at 50 per cent. When the patients who did not require a further surgical procedure are excluded, the symptomatic recurrence rate was found to be 16 per cent for total proximal nail bed ablation compared with 25 per cent for Winograd single wedge resection and 50 per cent for Winograd double wedge resection.

Table III: RESULTS OF NAIL BED ABLATION PROCEDURES

Surgical procedure	Patients No.	Patients %	Nail regrowth No.	Nail regrowth %	Further operation* No.	Further operation* %
Single wedge resection	56	35	15	27	14	25
Double wedge resection	8	5	4	50	4	50
Total proximal nail bed ablation	94	60	25	27	15	16

* Symptomatic recurrence rate.

Table IV: TREATMENT OF SYMPTOMATIC RECURRENCE FOLLOWING NAIL BED ABLATION PROCEDURES

	Initial procedure					
	SWR (56 patients)		DWR (8 patients)		TPNA (94 patients)	
	No.	%	No.	%	No.	%
Further operation required	14	25	4	50	15	16
Second procedure	3	9	1	3	29	88
Recurrence	0		0		10	34·5
Third procedure	0		0		9	
Recurrence	0		0		0	

SWR, Single wedge resection. DWR, Double wedge resection. TPNA, Total proximal nail bed ablation.

Of the 33 patients with symptomatic recurrence requiring further surgery, 88 per cent were submitted to a total proximal nail bed ablation, with a recurrence rate of 34·5 per cent (*Table IV*). Ninety per cent of these recurrences were submitted to further total proximal nail bed ablation following which there were no recurrences.

Sepsis

Forty-five per cent of patients admitted for treatment of their ingrowing toenails had sepsis of the nail folds recorded at admission. Of the 158 patients submitted to nail bed ablation procedures, 28 per cent had sepsis present at the time of surgery. The sepsis had no effect on the rate of recurrence of ingrowing toenail.

Discussion

The epidemiological findings in *Table I* and *Fig. 1* show that the sample studied was similar to previously reported groups of patients suffering from ingrowing toenails (Fowler, 1958; Lloyd-Davies and Brill, 1963; Townsend and Scott, 1966). The predominance of

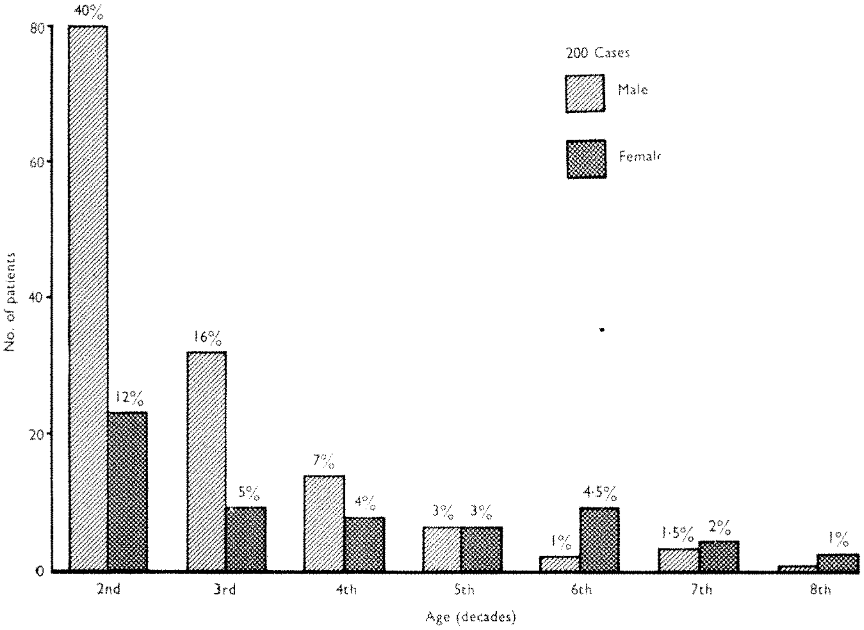

Fig. 1. Age and sex distribution of the patients with an ingrowing toenail.

males between the ages of 11 and 30 (56 per cent of patients) must be regarded as an important factor in planning a management policy. A painful ingrowing toenail which is inefficiently treated and requires numerous visits to hospital could well have a significant detrimental effect on education, career prospects and recreational activities in this group.

In this survey the recurrence rate of symptomatic ingrowing toenail following one avulsion was 64 per cent. However, cure is not the only aim of simple nail avulsion (Lloyd-Davies and Brill, 1963; Scott, 1968; Lepidus, 1972). The rapid relief of symptoms and the eradication of infection achieved by avulsion are important factors to be considered when contemplating the use of this treatment. For these reasons we feel that simple avulsion of the toenail has a definite place as a primary surgical procedure. Avulsion can easily be carried out on an outpatient basis under a local anaesthetic, unless infection has spread proximal to the interphalangeal joint, when a general anaesthetic should be used.

The importance of explaining to the patient simple conservative care of the new nail as it grows has been stressed elsewhere, and a follow-up clinic visit at 6 months to assess the success of the treatment is advised (Lloyd-Davies and Brill, 1963). If the condition has recurred and is causing symptoms, then more definitive surgery is called for. Our results show that the recurrence rate after a second avulsion at the same site was 80 per cent and is so high that further avulsion alone has little to offer. Some form of nail bed ablation should therefore be advised. A second avulsion is only indicated to eradicate a persistent and severe infection and to relieve symptoms prior to a more definitive procedure in the next few weeks. It is very difficult to justify more than two simple avulsions at the same site.

In this survey the commonest and most successful nail bed ablation procedure employed was total proximal nail bed ablation (Zadik, 1950), with a symptomatic recurrence rate of 16 per cent. This relatively high rate of recurrence is probably due in part to the lack of technical expertise of the junior surgical staff.

Winograd single wedge resection gave a higher symptomatic recurrence rate of 25 per cent, but may nevertheless be justifiable when performed properly in patients whose symptoms and signs have always been localized to one nail fold and who are loath to forfeit the whole of the nail. The results of Winograd double wedge resection suggest that this procedure should be abandoned in favour of total proximal nail bed ablation, although a large number of cases would be needed to confirm this impression.

Ninety-seven per cent of the nail bed ablations were performed under a general anaesthetic. This is a remarkably high figure when one considers that the anaesthesia for these procedures need be no greater than for a simple avulsion of a toenail, which is commonly performed under local anaesthesia. The use of local anaesthesia, sepsis permitting, allows satisfactory nail bed ablations to be carried out at an outpatient theatre session or on a day case basis, with minimal inconvenience to the patient and significant saving of the anaesthetist's time.

Fifty-five patients in our series were subjected to nail bed ablation without a previous avulsion of the toenail. It could be argued from our figures that approximately 20 of these patients would have regrown a normal nail if simple avulsion had been carried out as the initial surgical procedure.

In cases of troublesome recurrence following any of the ablation procedures, a total proximal nail bed ablation was commonly performed (88 per cent of patients), with a recurrence rate of 34·5 per cent. Townsend and Scott (1966) have stated that repetition of total proximal nail bed ablation for recurrence often proves unsatisfactory and recommend the use of the Symes terminal amputation procedure as reported by Thomson and Terwilliger (1951), and found satisfactory by Rees (1964).

Our results indicate that sepsis present at the time of a nail bed ablation procedure does not lead to an increased incidence of recurrence, as suggested by Townsend and Scott (1966). Moreover, the incidence of postoperative sepsis in our cases was surprisingly low and on no occasion was infection difficult to eradicate. The practice of performing a second avulsion on a recurrent septic ingrowing toenail 2–3 weeks before nail bed ablation, thereby rendering the nail bed clean, is, however, preferable to operating on a septic toe. This avulsion can be performed at the 6-month clinic visit or at a re-referral clinic visit and therefore does not unduly prolong the definitive surgery.

The outline of our management policy for cases of ingrowing toenail referred to the surgical clinic is now as follows:

1. Simple avulsion under local anaesthetic if there has been no previous surgical treatment.
2. Advice regarding conservative management of the new nail plus a 6-month clinic visit for assessment of the new nail growth.
3. Nail bed ablation under a local anaesthetic is advised for recurrent ingrowing toenails.
4. Septic recurrent ingrowing toenails are avulsed under local anaesthetic if possible and definitive surgery postponed for 2–3 weeks.

The use of this policy as a broad outline should result in the majority of cases of ingrowing toenail referred to surgical clinics being treated with minimal delay and inconvenience to the patient. A greater awareness by the junior surgical staff of the problems involved in the treatment of this annoying condition may well lead to improved management in the future.

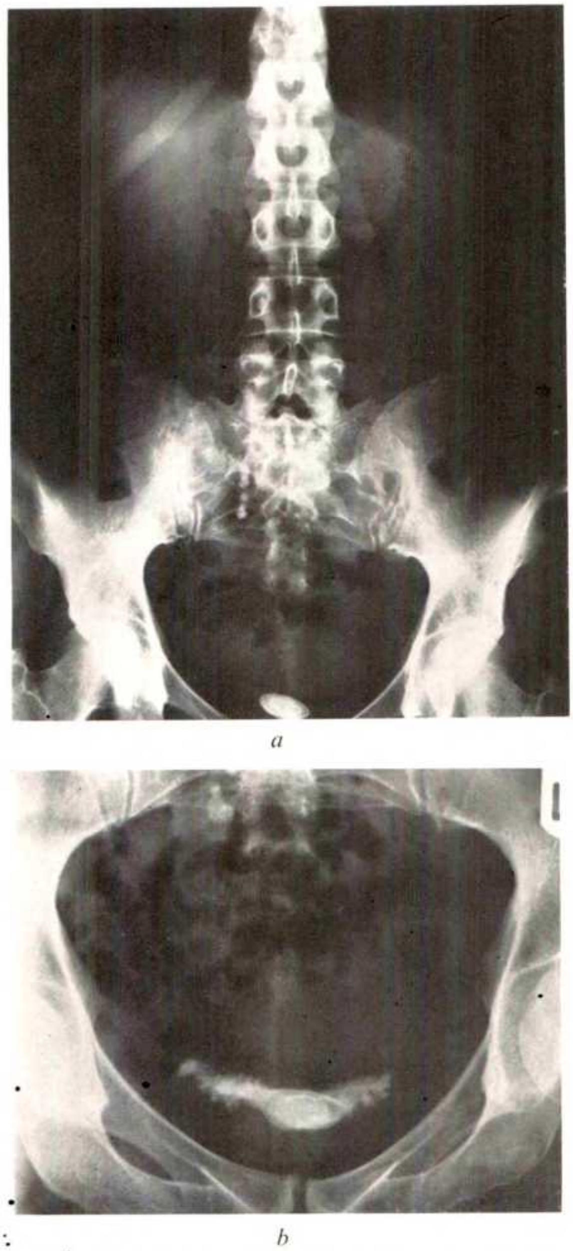
Hanging bladder stone formed around Mersilene mesh

P. P. DONGAONKAR*

FORMATION of a vesical calculus around a foreign body in the bladder is a well-known condition. Levack (1955) reported 2 cases of hanging bladder stones formed on unabsorbable suture and ligature. Weston (1957) reported another case of a similar nature. Chute (1962) published details of 8 cases of bladder calculi found around the fragments of ruptured Foley catheter balloons. Kiryabwire (1969) published a similar case of stone formation around a foreign body. Asopa (1965) described a case of formation of stone around a portion of stem of a plant, and Sood (1970) described the formation of a stone around a hair-pin; both of these foreign bodies were introduced into the bladder per urethra. A case is presented in which a bladder stone formed around a Mersilene mesh.



a

b

Fig. 1. *a*, Straight X-ray of the abdomen showing a calculus in the region of the bladder. *b*, Postmicturition intravenous pyelogram showing a calculus in the bladder.

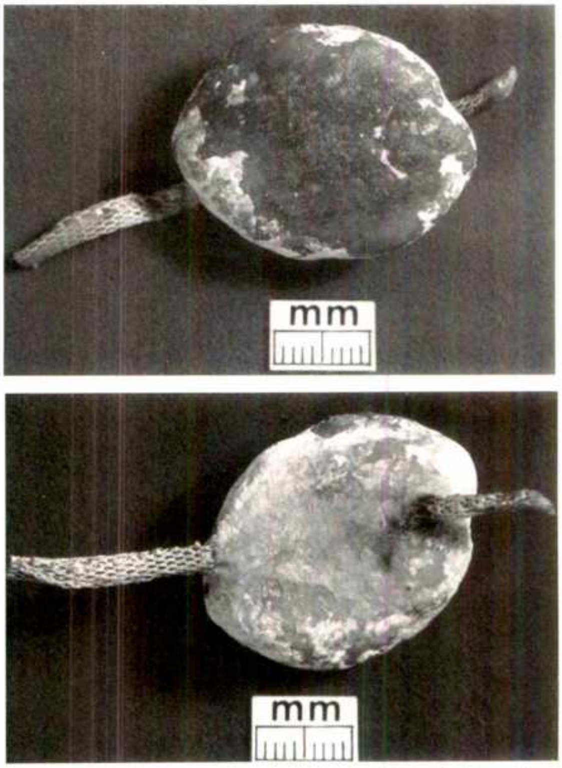


Fig. 2. Calculus showing incorporation of Mersilene mesh.

Case report

The patient, a 43-year-old married woman, presented at the Surgical Outpatients' Clinic, Rotherham Hospital, in 1974 with a history of urinary discomfort and haematuria on two occasions. She had had frequency of micturition for 2 years. In 1971 a urethral sling had been inserted for stress incontinence and the material used was Mersilene mesh. The stress incontinence had improved for a few months, but frequency and dysuria had continued.

---

* Rotherham Hospital, Yorkshire.

Straight X-ray of the abdomen and an intravenous pyelogram were performed which showed a large calculus in the bladder (*Fig.* 1). Both kidneys were functioning normally. Cystoscopy was performed and this confirmed the presence of a bladder stone. Suprapubic cystostomy was undertaken on 25 February 1974. It became apparent that there was a bladder stone which was hanging from the anterior wall of the bladder by two Mersilene slings. The stone was removed along with the Mersilene slings (*Fig.* 2). The patient's postoperative course was uneventful.

Conclusion

Mersilene mesh is being widely used for sling operations, but this would appear to be the first recorded case in the literature of the formation of a stone around Mersilene mesh protruding into the bladder.

Acknowledgements

I am grateful for the help and advice of Mr C. C. Rigby, Consultant Surgeon, Rotherham Hospital, and Mr D. Ballantine, Consultant Gynaecologist, Moorgate General Hospital, Rotherham, and for permitting me to report their patient.

Reviews and notices of books

Orthopaedic Surgery

Edward L. Compere, California. 210×145 mm. Pp. 323, with 90 illustrations. 1974. London: Lloyd-Luke. £12·15.

THE title is misleading; this is essentially a handbook of operative surgery. The operations that the author has employed in his own practice are described, but many that are part of the standard orthopaedic repertoire are omitted. This policy seriously impairs the usefulness of the handbook. For many orthopaedic disabilities a number of operations are available and the selection of the correct procedure requires careful judgement. A trainee surgeon will look in vain for this information and will find the description of some of the techniques inadequate, though this is remedied to some degree by the numerous illustrations.

The reviewer is at odds with a number of statements. In anterior arthrodesis of the cervical spine, the trachea, oesophagus and thyroid gland are retracted medially, not laterally. A medial meniscectomy, as here described, becomes a major attack on the knee joint, which is not necessary for the average bucket handle tear.

The final chapter on 'Errors and safeguards in orthopaedic surgery' contains both good and bad advice. Volkmann's contracture is usually caused by an arterial injury and not venous stasis, and the release of tight dressings and plaster may not be adequate. A surgeon who follows the instructions in the paragraph on 'Amputation and the certainty of the diagnosis or malignancy' may be tempted to delay amputation for a malignant tumour because of equivocal radiographic appearances or the absence of severe pain, when the histological diagnosis is not in doubt.

R. BARNES

Bonney's Gynaecological Surgery

Edited John Howkings, London, and Sir John Stallworthy, London. Eighth edition. 234×155 mm. Pp. 868+x, with 507 illustrations. 1974. London: Baillière Tindall. £11.

PREVIOUS editions of this textbook on operative gynaecology have been regarded internationally as major reference works. Undoubtedly Bonney must be recognized as one of the great men of surgery, and perhaps the one who contributed most to the development of techniques of gynaecological surgery. The editors in their preface regard this eighth edition as 'possibly the final tribute of two pupils to their master, Victor Bonney', and certainly this edition lives up to its past reputation and indeed shows valuable innovations.

Despite quite drastic revision, some original text from previous editions, including the opening chapter on general operative considerations, can be found and many of the illustrations are still Bonney's originals. Human frailties in the editorial process creep into the best-organized volumes, and the reviewer found this no exception when, by chance, he discovered the interchange of captions between Figs. 145 and 146.

It is ten years since the last edition and this new volume reflects well the changes in thought and practice over this period. A good example of the revision is the chapter on 'The radical abdominal operation for carcinoma of the cervix' which now contains a very full account of the use and results of radiotherapy in association with surgery.

The last three chapters of the seventh edition have been dropped (blood transfusion, water and electrolytes in gynaecological surgery, radiotherapy of gynaecological conditions) and one chapter (31) now replaces two separate chapters on post-operative complications—general. The new chapter on 'Post-operative complications: cardiovascular system' is more or less unchanged in the first part but then goes on to include an excellent contribution on thrombo-embolism written by John Bonnar.

As indicated, revision has been extensive—even the reference to 'catgut blisters' has been updated! Newer techniques such as laparoscopy and vacuum curettage receive mention, and the personal interests of one of the editors in medical defence can be detected in reference to medicolegal aspects in at least one chapter.

This is an excellent book and must still be one of the best works on gynaecological surgery in the world. Certainly it should be available in the surgeons' rooms of general surgical and gynaecological departments alike, where it will surely give information, advice and possibly comfort to the surgeons faced by an unexpected gynaecological emergency.

D. V. I. FAIRWEATHER

Practical Surgical Management

A. M. C. Macgregor, Florida. Second edition. 180×120 mm. Pp. 150+ix. 1974. Edinburgh: Churchill Livingstone. £1·50.

THIS little book is full of useful information and fits snugly into a white coat pocket. These are two essential requirements for a book designed for house surgeons.

The arrangement is logical and the first chapter on 'Pre-operative management' consists largely of check-lists of investigations that may be required. 'Organisation of theatre' follows and is brief and to the point. 'Post-operative management' is dealt with next and again is composed of lists of such things as when to remove drains, drips, sutures and indications of recovery or complications, etc. 'Fluid and electrolyte management' followed by 'Intensive care' complete the section dealing with the care associated with operation. Another very brief chapter, this time dealing with 'Administration' is followed by one entitled 'Data'. The data referred to are a collection of normal values for haematology, blood and urinary chemistry, CSF and various other tests. All this information is useful, mainly accurate and helpful if some of the qualifications necessary to interpret this kind of information are remembered. Finally there is a chapter on 'Drugs' which is by no means complete but a useful starting point nevertheless.

The main point of such a book as this is to provide a framework around which the idiosyncrasies peculiar to a particular job can be built. With this point in mind perhaps a little spare space consisting of a few blank pages for notes and jottings would be helpful. Perhaps also in the next edition a note about SI units might be included, but with these two suggestions made, the book is recommended as a good buy for the house surgeon at the beginning of his job.

C. WASTELL

Transfusion of Blood Preserved by Freezing

S. Sumida, Fukuoka, Japan. 255×180 mm. Pp. 92+xiv, with 117 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.58.

THIS elegantly produced monograph is an account of how Dr Sumida organized the first frozen blood bank in Japan. Inspired by an address given by that singular pioneer, Dr Charles Huggins of Boston, at a meeting of the Japan Society for Blood Transfusion in 1965, Dr Sumida lost no time in visiting Massachusetts General Hospital where he acquired the necessary skills and knowledge to set up a replica of the Huggins system for handling frozen cells for transfusion in Fukuoka.

For anyone wishing to follow his example, here is an explicit step-by-step description of the method, illustrated with excellent photographs and simple diagrams. The author has reappraised each step of the procedure by his own laboratory and clinical investigations, and a particularly interesting chapter is devoted to original observations on the changing morphology of red and white blood cells under the cryomicroscope.

While much of the technical section is concerned with the Huggins system which requires a high concentration of glycerol as the protective agent, a slow rate of freezing and mechanical refrigeration of the product at −80 °C, the author does give his more limited experience of the low glycerol rapid-freezing technique in liquid nitrogen at −150 °C. The parameters used to judge the quality of the final blood product, such as red cell recovery, post-transfusion survival, ATP content of red cells, etc., all favour the liquid nitrogen technique.

Apart from a single chapter dealing with the clinical advantages and disadvantages of frozen/thawed red cells, the book is mainly of interest to the technically minded. In the United Kingdom clinicians tend to leave decisions on methodology in blood banking to their colleagues in the National Blood Transfusion Service, and, in this sense, the decisions have already been taken as the five centres in this country now operating frozen blood banks have opted for the liquid nitrogen technique based on Krijnen's method, with local variations.

A chapter on techniques for freezing platelets is stimulating, but it is clear that the final choice of protective agent is still undecided and that the yield of viable platelets after freezing is disappointing.

W. J. JENKINS

The Treatment of Breast Cancer

Edited Sir Hedley Atkins. 210 × 145 mm. Pp. 222. 1974. Lancaster: Medical and Technical Publishing Company. £7·50.

AN introduction to this volume states: 'The aim is to attempt to bridge the gap between standard textbooks and research papers and to provide an assessment of the various methods available'; in this it succeeds admirably. The authors, each a recognized authority on a particular aspect of breast cancer, review the evidence to support prevailing attitudes to the disease, and interest is maintained by leaving the reader to draw his own conclusions on the presented evidence.

A recurring theme in the text is the need for reappraisal of many theories in relation to breast cancer, which through repetition and long usage have come to be accepted as facts on which many of our principles for the management of the disease are founded. The reader's attention is repeatedly drawn to the urgent need for identification of the biological factors which constitute host resistance to the disease. The authors deal with surgical treatment, radiotherapy, endocrine therapy, chemotherapy and finally with tests of prediction in relation to breast cancer.

From a personal viewpoint, the reviewer found the chapter on tests of prediction particularly stimulating and a challenge to the future. In the present state of our knowledge it is accepted as necessary to put the salient evidence in front of the reader, but in this particular field one must leave its interpretation to experts on the subject, such as the author and his colleagues. Whilst concentrating mainly on endocrine status in relation to breast cancer, the author concedes that other factors such as viral infection and immune response may be equally important.

This volume is to be recommended for every ward library as a reasoned guide to the problem of breast cancer at this time. It highlights the need for combined effort in diagnosis and treatment in a field which is no longer the sole province of the surgeon and radiotherapist. It will be of particular interest to all oncologists and it is hoped that future editions of this book will maintain the excellence of the first.

JAMES F. PHILIP

Diagnosis and Early Management of Trauma Emergencies. A Manual for the Emergency Service

Edited Robert J. Touloukian and Thomas J. Krizek. 230 × 150 mm. Pp. 149 + vii, with 23 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. $10.75 cloth. $6.75 paper.

EVERY doctor working in an accident and emergency department needs a guidebook; something like an instruction manual, concise, factual, lucid and didactic. The present book aims at just this target; it achieves a near miss. Brevity has been achieved by restricting the discussion to trauma; most British casualty officers (the book is manifestly transatlantic) will regret this limitation even though the title has warned them to expect it.

There are only three chapters. The first is wide-ranging and fascinating; in 19 pages it touches on triage, responsibility, medicolegal liability and even security. The second deals with ambulatory problems including open wounds, battered babies (? ambulatory), hand infections, maxillofacial trauma and eye injuries. The third and longest chapter deals with life-threatening emergencies: the obstructed airway, shock, head, chest and abdominal injuries, as well as fractures and dislocations.

Much of the guidance (apart from a cursory and actively misleading account of the care of the injured hand) is sound, but access to the information is sometimes difficult. The authors clearly try to achieve a systematic approach and often succeed, but when the going gets rough they sometimes lose heart. The line drawings are striking and useful, but extraordinarily inelegant.

This book needs to be re-edited, with the chapters and headings rearranged and in a format designed to fit a white coat pocket. Only then will the authors' single-minded concentration on the early management of the injured patient, their sound and sensible approach to severe injuries and their interesting views on organization gain proper recognition and enjoy widespread application.

A. GRAHAM APLEY

Clinical Neuro-surgery

Congress of Neurological Surgeons, Volume 21, Honolulu, Hawaii, 1973. 228 × 150 mm. Pp. 387 + xv. Illustrated. 1974. Baltimore: Williams & Wilkins. $19.50.

THIS book reports the annual meeting of the Congress of Neurological Surgeons. This society is unusual in several respects; its office bearers are all comparatively young (by statute) and its meetings are specifically planned as an educational exercise. Consequently, this annual publication is eagerly awaited and seldom disappoints. As is the usual style, this volume has several papers on each of a limited number of topics. Surgery of the pituitary, aneurysm surgery and the management of pain are this year's foci of interest. Each chapter is long enough to develop its theme satisfactorily, as well as to illustrate it, and has adequate references. Most describe the author's personal experience and attitude to the topic under discussion, and it is useful to read advocates of alternative techniques in succeeding chapters. There are two review articles, on the immunological and on the viral aspects of brain tumours—a reminder that whilst so much effort has gone into stereotaxic surgery and the management of aneurysms in the past two decades there has been little progress in the management of tumours. This volume should be of interest to many other surgeons, in view of the discussions on pain and on endocrine aspects of pituitary surgery.

BRYAN JENNETT

Chirurgie der Gegenwart

Edited R. Zenker, München, F. Deucher, Aarau, and W. Schink, Köln. 260 × 180 mm. Vols 4 and 5, pp. 22, 47, 50 and 35. Illustrated. 1974. München: Urban & Schwarzenberg. No price given.

FOUR further chapters have now been published. These include a detailed discussion of metabolic changes in the skeleton and the various disease processes which reflect upon skeletal changes. Three other chapters are related to orthopaedics. These cover injuries to the central nervous system in relation to vertebral damage, the management of pseudo-arthroses and finally the management of fractures of the lower limb. The chapter on pseudo-arthroses contains numerous rather horrifying illustrations but the writers do point out the mistakes made at the time of initial treatment and in relation to the causation of a failure to unite. The emphasis in the chapter on fractures of the tibia and the femur is definitely on the operative side and conservative management gets little mention.

It is unfortunate that the chapters of this multi-volume work are being numbered in relation to their time of publication so that the final numbering may appear rather irrational. However, this is obviously going to be a reference book rather than one to be read from cover to cover, so that the detailed numbering may not matter so much.

H. B. ECKSTEIN

The Myocardium: Failure and Infarction

Edited E. Braunwald, MD, Boston, with the collaboration of Amy Selwyn, Hospital Practice. 280 × 210 mm. Pp. 409 + xviii. with 350 illustrations. 1974. Reading: W. H. Freeman and Company. £10·40.

THIS is a most unusual book because the chapters originally appeared as individual papers in *Hospital Practice*. The authors are an extremely distinguished group and all of them have revived and modernized their articles for this volume. The coverage is broad, section I dealing with cardiac contraction mechanisms from ultrastructure through biochemistry, calcium metabolism and the biochemical basis of heart failure. Section II deals with physiological mechanisms of heart failure, with Dr Braunwald himself contributing a chapter on the autonomic nervous system in heart failure. Sections follow on the clinical manifestations of heart failure in adults and children, in heart muscle disease and in cor pulmonale. The treatment of heart failure follows. Section V gets down to the meat of the book and deals very fully with atherosclerosis and the mechanisms of myocardial infarction. It starts with the development of the atherosclerotic plaque and goes through primary prevention in children, the role of platelets and thrombosis, the pathology of the coronary arteries in fatal ischaemic heart disease, the genetic aspects of hyperlipidaemia and, finally, aggressive behaviour as a risk factor. The next section deals with what follows myocardial infarction: the biochemical and morphological changes, the haemodynamic consequences and sudden death. Section VII deals with treatment from the coronary care unit through anti-arrhythmic drugs, the management of arrhythmias, the present status of anti-thrombotic therapy and protection of the ischaemic myocardium. The surgical aspects are not forgotten and we find a chapter on myocardial revascularization from the Cleveland Clinic and the recognition and surgical treatment of imminent infarction. Mechanical assistance of the failing circulation and surgical myocardial revascularization during post-infarction shock conclude the surgical aspects of coronary artery disease. Finally, rehabilitation is not forgotten.

Dr Braunwald and his collaborator Amy Selwyn have done a splendid job of integration between the different authors' contributions and there is abundant cross-referencing to the material in other chapters when this is closely related. Dr Braunwald and his team are to be congratulated on achieving such remarkable balance and cohesion between the different chapters. The illustrations also are of a uniform excellence and are printed in a pleasing duo-tone which adds to their clarity. There are no references at the ends of the chapters. Selected reference sources for each chapter are collected together at the end of the book.

This book is highly recommended for covering the topic which it sets out to treat in such a readable and informative way and it will be of interest to both general physicians and cardiologists as well as to cardiac surgeons wishing to extend their vision beyond the operating table and to all students of the heart and circulation. Its price at £10·40 is not excessive for these days.

C. M. OAKLEY

Vascular Malformations (Angiodysplasias)

Edited E. Malan, Milan. 240 × 170 mm. Pp. 213, with 176 illustrations. 1974. Milan: Carlo Erba Foundation. No price given.

PROFESSOR MALAN edits this review of his experience of vascular malformations which must be unique. He is assisted by eighteen contributors, mostly his colleagues in Parma and Milan. He has collected the amazing number of 451 vascular malformations which, in most surgeons' experience, are relatively rare. The clinical aspects are comprehensively described and the illustrations are beautifully depicted. This is a monumental work, an accumulation of clinical experience over many years. There is a most useful chapter on malformations affecting the head and neck. This will no doubt be accepted as the definitive work on the presentation and treatment of vascular malformations. Anyone seeing and treating these conditions must consult this work. The bibliography is comprehensive and invaluable.

Minor criticisms must be made but in no way detract from the overall worth of this monograph. The classification is cumbersome, difficult to absorb and difficult to remember. The chapter on aetiology is unconvincing and does not show any advance over the past 25 years. It is still not possible to say where the shunts are sited in cases of diffuse arteriovenous communications. There is no mention of the use of ultrasound in the investigation of arteriovenous shunting. It is disappointing that Professor Malan is disenchanted with his imaginative operation of 'deafferentriation', that is, extensive division of arterial branches in cases of diffuse congenital arteriovenous anastomoses. Lastly, a small point, but the binding is poor and came apart during the reviewer's reading of the book.

L. T. COTTON

Atlas of Hand Surgery

Robert A. Chase, MD, California. 310 × 240 mm. Pp. 438 + xi. Illustrated. 1973. London: W. B. Saunders Company. £12·75.

THIS *Atlas of Hand Surgery* by Robert A. Chase is a well-illustrated and comprehensive volume. It covers all aspects of hand surgery from trauma to the elective surgery of such conditions as rheumatoid arthritis, Dupuytren's contracture and the reconstructive surgery of irreparable nerve lesions. The descriptive text is well amplified by clear diagrams and photographs. It reflects current opinion but unfortunately does not include a bibliography or list of references. Nevertheless, as the author states, 'the material presented in this atlas is based on case experiences'.

This book offers sound practical advice, and as such should prove a useful addition to a hospital library. For those concerned with the day-to-day management of problems of hand surgery it will be most valuable.

DONAL BROOKS

Emergency Abdominal Surgery, in Infancy, Childhood and Adult Life

Peter F. Jones, Aberdeen. 240 × 165 mm. Pp. 808 + xx. Illustrated. 1974. Oxford: Blackwell Scientific Publications. £13·50.

THE first objective of the author of this excellent book was to give the trainee surgeon a background knowledge of the whole field of emergency abdominal surgery. The second was to provide a handbook for consultation on specific problems and detailed advice on management and technique. Both objectives have been achieved with most unusual success. Writing with the confidence and competence based on his experience of emergency surgery over the past quarter of a century, Mr Jones has described the methods he has used and their advantages and disadvantages with refreshing candour and objectivity. Of course, no other surgeon will agree with all he says, but no one can doubt that the advice he gives is sound and comprehensive for those for whom he has written, and is often better than can be found in other books of this kind. In the sense that she is said to have inflicted every one of her recipes on her own family, this book could fairly and in no unkindly way be called the 'Mrs Beeton' of modern emergency abdominal surgery and is unhesitatingly recommended to the surgical maiden of today. The whole subject is covered including pre- and postoperative treatment and emergencies in the newborn, infancy and childhood. The chapters on acute appendicitis and intestinal obstruction are particularly good, and there are very helpful sections on the acute abdomen in pregnancy and the puerperium, gynaecological disorders, medical causes of acute abdominal symptoms and urological emergencies.

There are good and very helpful line drawings of the details of many operative techniques and interesting historical notes, and the references to the important original accounts of diseases and operations will be of much value to the young surgeons for whom this book is primarily written.

This book can be recommended most strongly to the surgeon in training, especially those who for whatever reason lack supervision, and to any surgeon who has to deal with the acute abdominal emergency. It should be in every hospital library for those who cannot afford their own copy.

A. W. WILKINSON

Handbook of Psychiatry

Edited Philip Solomon, San Diego, and Vernon D. Patch, Boston. Third edition. 210 × 135 mm. Pp. 706. 1974. Los Altos, California: Lange Medical Publications. $8.

THIS is the third edition of a comprehensive handbook of psychiatry that manages to compress a vast amount of information into a little over 700 small pages. There are forty short didactic chapters by a large number of authors who succeed in covering most topics in a thorough and eclectic manner, although of necessity in a book of this size covering so much there can be comparatively little discussion of many controversial issues. One has the impression that in the attempt to get completeness of coverage, some authors are not writing from their own experience but quoting from not always accurately remembered student textbooks. The brief notes on some aspects of epilepsy, for example, do not fairly cover the somewhat complex problems that many such patients have. Likewise, although there is a short interesting note on the dynamics of the surgeon–patient relationship, there is nothing on the psychiatric aspects of pain, which are certainly of interest to the surgeon. One of the new chapters is on transcultural psychiatry, and this seems to fall into the common fault of assuming that a foreign or immigrant patient will necessarily have specific and subtle problems which cannot be assessed by orthodox methods. No reference is made to many of the current epidemiological studies in different countries; for example, of schizophrenia by the WHO. Of necessity, the administrative and legal aspects of psychiatry entirely reflect the American scene.

Medical students in this country will thus find this book of only limited value, though it is certainly better than most of the short texts that are popular in this country. Most chapters have quite lengthy references which, if the student has time to read some of them, might act as a useful check against the didactic approach of the main text. The relative absence of references in comparable British books is to be deplored as it tends to discourage the student from reading more widely on his own account.

D. A. POND

Surgical Pathology

Lauren V. Ackerman, New York and St Louis, and Juan Rosai, St Louis. Fifth edition. 260 × 200 mm. Pp. 1394+xii, with 1392 illustrations. 1974. London: Henry Kimpton. £21·60.

THERE are some books that rapidly establish themselves as definitive texts. Ackerman's *Surgical Pathology* is such a work. When it first appeared in 1953 it was obvious that this was not yet another book written about surgical aspects of pathology ('the pathology of the living' as Dr Ackerman neatly calls it). Instead, here was the subject looked at, and described, by someone who was actually working in the surgical pathology laboratory, and who knew the problems faced by both surgeon and pathologist in diagnosis. This book is an invaluable aid to anyone with such a problem; its place is on the bench (next to the cut-up area and the microscope) rather than in the library or in a bookcase.

Having said that, it is still very readable with a lively style and sense of humour; for example, in the description of the indications for frozen section where, having emphasized that the technique is only indicated if it affects treatment then and there, the authors state that it should not be used 'to satisfy the surgeon's intellectual curiosity, or to prove that the pathologist is in the hospital'.

The present edition maintains the previous high standards and the references are up to date (and quote from the current British and American literature, which is not always the case with North American books). The major areas of pathology are covered with the exception of the ear; and, because biopsies from this site are such a common diagnostic problem, it seems worth while to suggest that the next edition includes a small chapter on aural pathology. Wisely, there are no plates in colour, but the black and white photographs and photomicrographs are very clear. It would, however, be helpful to have an indication of the actual size of gross specimens (e.g. Fig. 855, p. 854 is described as 'large', but no scale is included). These are but minor matters in a work to which everyone concerned with surgical pathology must refer.

P. M. SUTTON

Surgical Treatment of Facial Injuries

V. H. Kazanjian and J. M. Converse, New York. Third edition. 252 × 175 mm. Pp. 1482+xxxiii. Illustrated. 1974. Baltimore: Williams & Wilkins. £30.

A SCIENTIFIC treatise that reaches its third edition in twenty years under the baton of the original authors is a tribute both to them and to the value of the work itself. So it is with the *Surgical Treatment of Facial Injuries*, already established as a classic, and which now is a record of 75 years' combined personal experience of Dr Kazanjian and Dr Converse.

It might seem strange that an apparently small section of surgery requires 1500 pages in two volumes fully to account for all its activities but it does. The early chapters deal with basic principles of the processes of healing, the art and craft of facial surgery, as well as a tribute to anaesthesia. There follows an important dissertation on the emergency management of facial injury, a subject which perhaps should be better understood in casualty departments. The complexities of facial fractures are dealt with in some 200 pages and the details of many techniques of immobilization are described and well illustrated. As is to be expected the dental aspects of jaw fractures are clearly and carefully outlined.

A consideration of facial injuries in childhood serves to introduce the reader to the problems of facial growth and to the late effects of injury. One aspect of this subject which might have warranted a mention is the effect of irradiation on the young face, not only upon the soft tissues but upon skeletal development.

A section on radiography of facial bones contributed by Dr J. Zizmor presents the essential outlines of this diagnostic technique. It includes a discussion on pantomography which is now an invaluable adjunct to the study of skeletal and dental aberrations. There follow six chapters on general principles of reconstructive surgery in which is condensed the fundamental theory and techniques of tissue transplantation. All graftable tissues are discussed and there is a useful section on skin transplantation using the pedicle flap methods and their application to facial surgery. The remainder of the text deals with the correction of established facial deformities which follow trauma. These are set out on an anatomical basis and are as complete a record of the subject as will be found anywhere.

The various conditions are amply illustrated with line drawings and with photographs from the authors' vast library and many cases of special interest are to be found.

For the young surgeon here is a book which may be read from cover to cover with interest and without boredom. For the established practitioner here is an essential part of his armamentarium to which he will undoubtedly refer until the advent of the fourth edition which in due time will surely appear.

J. N. BARRON

Dupuytren's Disease

Edited J. T. Hueston and R. Tubiana. 275 × 210 mm. Pp. 167. Illustrated. 1974. Edinburgh: Churchill Livingstone. £7.

THIS monograph under the joint Editorship of John Hueston and Raoul Tubiana is based on the 1966 SICOT papers presented in Paris and subsequently produced by the Group d'Etude de la Main in French. This is the first English edition but is not simply an English translation of the previous French publication. This edition has been greatly expanded by contributions from well-known authorities on the subject and by revision of the earlier texts. The result is a fascinating narrative starting with a thumbnail sketch of the Baron himself and thereafter including all aspects of the disease and its treatment.

There is certainly no more authoritative work on the subject in the English language and it is doubtful whether in the years to come it will be superseded. Each contributor has added something of worth or exposed some new facet of 'this mysterious disease'. Although it is almost a century and a quarter since Dupuytren described a condition which he believed to be primarily an affection of the palmar fascia it seems strange that, while the treatment has been clarified over the years, the aetiology still remains obscure.

This is a splendid monograph, immaculately produced and illustrated and one that those who are concerned with the surgery of the hand will wish to have in their library.

DONAL BROOKS

The Practical Management of Head Injuries

John M. Potter. Third edition. 184×125 mm. Pp. 98+xiv, with 8 illustrations. 1974. London: Lloyd-Luke. £2.

THE appearance of the third edition of Mr Potter's well-known and valuable little book is to be warmly welcomed, not only by the 'casualty officers, orthopaedic and general surgeons, general practitioners and senior nurses' for whom, as the introduction states, it is primarily intended, but also by many teachers of surgery, who, like the reviewer, have sought to recommend the book to undergraduates but have been dismayed to find the book out of print for far too long.

Since the first edition appeared in 1961 there have been a number of imitators (at least two from Australasia) who have published a 'slim volume' concerning the management of head injuries, but none has quite achieved the readability or the comprehensiveness that Mr Potter has provided within the space of 98 pages of text.

There is an introduction, four chapters, three short appendices and a good index. The chapters deal, in logical sequence, with management in the casualty department and in the ward, with complications and lastly with convalescence, rehabilitation and sequelae. The information given is precise and clear at every stage and above all is entirely practical and to the point.

Rightly, no attempt has been made to involve the reader in theoretical conceptions nor is the underlying pathology described in any detail, basic knowledge being assumed. Similarly, special aids to diagnosis such as the EEG, angiography, isotope scanning, etc., have been eschewed because, in the circumstances for which the book is primarily conceived, specialist advice and assistance may not be promptly available. However, as a minor point of criticism, times are changing and in many accident departments in the United Kingdom and elsewhere some or all of these aids are becoming better understood and increasingly utilized. Echo-encephalography is, nevertheless, mentioned, albeit with deserved reservations. Perhaps it is too much to hope that by the time the next edition appears the EMI scanner will have resolved some at least of our diagnostic difficulties in this field!

BERNARD HARRIES

1974 Year Book of Plastic and Reconstructive Surgery

Edited Kathryn Lyle Stephenson et al. 194×130 mm. Pp. 360, with 127 illustrations. 1974. London: Lloyd-Luke. £12·50.

IT might be thought that the quick and easy way of keeping up to date in a speciality is to purchase the Year Book dealing with your subject. An expensive method perhaps. In the present volume over 200 papers are reviewed (up to July 1973) under regional anatomical groupings—the head, neck and thorax, genitalia, limbs, with further sections on burns, shock, anaesthesia, wound healing, neoplasms and transplantation—a wide variety of topics. For the busy surgeon the book offers much, but makes difficult reading because so often the abstract is not a true precis of the published paper but a short extract. Even the 127 figures fail to clarify poorly written texts.

Many of the 200 publications relate to retrospective surveys which have little place today unless the conclusions can point the direction in which a proper clinical trial should be made, indicating new observations to be followed or present new concepts. In some papers the author has muddled actual numbers and percentages, a feature which the editors (all seven of them) should have corrected; often because the numbers were small the use of percentages give completely false impressions. Editorial comments follow many of the extracts but, in the reviewer's opinion, could be more detailed (what is the 'Lipshutz technic'?) and more telling. A short authoritative essay preceding each section would help to put into perspective the extracts that follow. Indeed, the problem of selection of papers for presentation in this form has not been solved by this issue, especially when one considers that techniques are reported which are well known and well documented in standard textbooks.

This compact and nicely bound volume can be recommended for the busy man who does not subscribe to journals or who has little time to read them.

JAMES CALNAN

The Physiology of the Joints. Volume 3. The Trunk and the Vertebral Column

I. A. Kapandji, Paris. Second edition. 275×220 mm. Pp. 251, with 397 illustrations. 1974. Edinburgh: Churchill Livingstone. £4.

THIS is an important publication. As Professor Merle D'Aubigne writes in his preface to the French edition, it 'is a dedicated work by Dr. Kapandji, the artist and teacher, who has not only imagination and a flair for mechanics, but also the ability to communicate his ideas in a precise and simple fashion'.

Although it may be trite to recall that anatomy may be the handmaiden of the surgeon, there is a danger that the systematic and topographic anatomy learnt on the cadaver may blind us to important aspects of the anatomy of function, in particular the biomechanics of muscle and joint activity in life.

This volume is the third of a series on the physiology of joints and deals with the trunk and vertebral column; the first dealt with the upper limb and the second with the lower limb. These volumes are in their second edition translated from the French. It is impossible to summarize the wealth of information and it is recommended most highly, in spite of the trifling irritation caused by the translator's occasional lapses, in particular the excessive use of the definite article, correct in the original French but irritating to an English reader.

Nevertheless, the message is crystal-clear and those interested in biomechanical problems will deepen their understanding as to how groups of muscles work in patterns as prime movers, antagonists or synergists.

As an illustrator of original ideas the author can have few medical peers.

L. KESSEL

Fluid, Electrolyte and Nutrient Therapy in Surgery

Edward E. Mason, MD, PhD, Iowa. 234 × 155 mm. Pp. 352+vi, with 55 illustrations. 1974. London: Henry Kimpton. £5·95.

THIS book emphasizes the surgeon's responsibility to have a clear understanding of the metabolic changes in his patients at all times. This is virtually a single author work by a practising surgeon with the exception of the last chapter. The aim of the book is to enable surgeons to handle metabolic problems more effectively.

The style at times becomes anecdotal and it is difficult to follow the reasons for including various sections in a book of this nature, as on occasions the reader is led into bypaths which are in themselves quite interesting.

The first section naturally deals with body composition and its measurement. Subjects such as fluid and electrolyte balance are covered adequately and in considerable detail. The section on nutrition, however, is somewhat limited. Many recent developments in amino-acid preparations for parenteral use are not dealt with, and there is no mention of the role of intravenous fat as an important calorie source in intravenous feeding programmes. Some of the problems of parenteral feeding are identified clearly.

There is a detailed chapter on intestinal bypass surgery for obesity which also contains an interesting diversion on the aetiology of recurrent peptic ulceration after gastric surgery.

The section on calcium and phosphorous metabolism goes far beyond the title of the volume and contains a detailed discussion of the diagnosis of primary hyperparathyroidism, the differential diagnosis of hypercalcaemia and the surgical management of primary hyperparathyroidism. This is a good chapter, but it is odd that this subject should be dealt with in such detail when fluid and electrolyte problems associated with other endocrine tumours are barely mentioned.

The style and presentation of this book preclude its use as an intensive care manual. It is unlikely that it will be used to seek help with specific problems as it is only in the last chapter that clear recommendations for definite problems are set out in any detail. However, this is an interesting, quite detailed book on a very important subject and could be a useful source book for postgraduate students reading in the overall field of fluid electrolyte and nutrient therapy.

IVAN D. A. JOHNSTON

Reviews and notices of books

The Genetics of Locomotive Disorders

C. O. Carter, London, and T. J. Fairbank, Cambridge. 160× 240 mm. Pp. 170+xii. 1974. London: Oxford University Press. £5.

THIS book is concerned with the inheritance of various diseases of bone, muscle, joints, nervous system and connective tissues. Most of the text is devoted to bone disorders, localized abnormalities of the limbs and syndromes involving the skeleton. The style is clear with a short section for each disease which includes a brief clinical description, the genetic information and the appropriate references at the end. It is not a textbook of diagnosis. There are no illustrations and only a few tables which deal with the analysis of genetic data. It is a reference book for those who, having diagnosed a particular disease, wish to know about the mode of inheritance. So much is acknowledged by the authors in their preface so the absence of clinical illustrations is not surprising. However, some comparative tables would have been useful for highlighting important clinical or genetic differences between rather similar diseases. This book will be most useful to clinical geneticists, orthopaedic surgeons, paediatricians and physicians interested in bone disease. There is not sufficient in it about joints to interest the rheumatologist and the genetics of connective tissue disorders is covered by McKusick in his very comprehensive monograph on that subject. Neurologists and neurosurgeons may prefer the earlier Oxford monograph which deals entirely with the inherited diseases of nerve and muscle. It is unlikely that a general surgeon would refer to it very often, but it will be a quick, easy and authoritative reference book for those with special interests in bone disorders and skeletal malformations.

D. P. BRENTON

Review of Medical Pharmacology

Frederick H. Meyers, San Francisco, Ernest Jawetz, San Francisco, and Alan Goldfien, San Francisco. Fourth edition. 260×180 mm. Pp. 721. Illustrated. 1974. Los Altos, California: Lange Medical Publications. No price given.

THIS is an eminently readable, though humourless, textbook. It is liberally illustrated with clear diagrams indicating drug structures and pharmacological concepts. Conventionally organized in sections it deals in different sections with drugs acting on different systems of the body, with chemotherapeutic agents, etc. None of the sections is unduly long, the aim being to present concise useful information. Accordingly, only one or two drugs having a particular action are discussed—this is a deliberate policy to avoid bewildering the student with lists of tranquillizers, antibiotics, etc. Each chapter ends with a short list of key references, so the information in the text could readily be expanded by the interested reader.

If the book has a fault it lies not so much with the authors as with the FDA, who so restrict the use of new drugs in the United States that the authors are forced to admit that propranolol is not approved for use in essential hypertension or in hyperthyroidism, and that bethanidine and clonidine are not available in the United States. This, naturally, reduces the reader's confidence in the personal experience of the authors.

Although the fourth edition appeared in 1974 it still does not contain any reference to such recent advances as the invention of drugs which block histamine H_2-receptors or the discovery that aspirin blocks prostaglandin synthesis, but these are minor points.

The book as a whole is a most valuable text.

J. H. WYLLIE

The Cutting Edge. Early History of the Surgeons of London

R. Theodore Beck, Surrey. 235×165 mm. Pp. 214+xvi. Illustrated. 1974. London: Lund Humphries Publishers. £6.

THIS book will appeal not only to the medical profession but also to the lay public, for it provides a fascinating and very interesting insight into the early history of healing.

The author, a well-known architect, has the right background to write such a book as this, for he is a past master of the Worshipful Company of Barbers, a life member of the Royal Archaeological Institute, Fellow of the Society of Antiquaries, Fellow of the Royal Society of Arts, Fellow of the Royal Institute of British Architects and a member of the Court of Common Council of the City of London. Theodore Beck, when Sheriff of London in 1969 was invited by the President and Council of the Royal College of Surgeons to give the Thomas Vicary lecture.

A laudatory foreword to this book is written by The Lord Mayor of London, Lord Mais, during his reign of office in 1973.

The early history of the barber-surgeons concerns the City of London to a great extent, and also the surgery of the battlefield during the Hundred Years' War. The author has vividly portrayed the extent of surgical operations during this period. Throughout the book the illustrations are of a high order and have been well chosen.

The traditional *Fair Book of Surgery* compiled by Thomas Morstede, the most eminent surgeon of the fifteenth century, was thought for centuries to have been lost but has been found and identified by the author in the Harleian Collection in the British Museum. It was written in 1446 and extensive extracts from this ancient book are quoted.

The series of events which led to the union of the Guild of Surgeons and the Barbers Company to form the Barber Surgeons Company in 1540 are well presented.

Perhaps one of the most useful parts of this book is the inclusion of biographical notes at the end of each chapter; these will be of real value to medical historians of the future. A concluding chapter describes the life and times of Thomas Vicary, Sergeant Surgeon to King Henry VIII, and his contemporaries. Theodore Beck should be warmly congratulated on writing this book, for he has added considerably to our knowledge of the early history of British Surgery.

CECIL WAKELEY

The Treatment of Prostatic Hypertrophy and Neoplasia

Edited J. E. Castro. 210×145 mm. Pp. 200+xii. Illustrated. 1974. Lancaster: Medical and Technical Publishing Company. £6·75.

ALTHOUGH numerous books have appeared on the various techniques of prostatic surgery, there has not been an attempt to collate all aspects into one small volume until now. In many ways this book represents a new, very readable and extremely up-to-date account of all that is known about the prostate, starting with an excellent summary of the biology and the pathological changes in both the benign and malignant glands. It is rare for the pros and cons of controversial therapeutic methods to be presented in successive chapters so clearly and so concisely.

An excellent description of the surgery of the benign hypertrophy of the prostate, including a full bibliography, leaves the future prostatectomist fully conversant with the various methods open to him.

Crysosurgery, a new method, is described in detail, listing the advantages and disadvantages of this rather novel form of therapy, and there is an excellent chapter on the conservative medical treatment by a contributor from the United States.

The whole subject of neoplasia is fully ventilated, an aspect which at the present time of re-evaluation of conventional methods of treatment, is extremely valuable. The radical surgical approach, the conservative approach and the various hormonal methods of control of the disseminated disease are explained clearly.

This volume merits careful reading by all scientists and clinicians who are interested in the recent observations and techniques of treatment of prostate disease. In the foreword the editor quotes Professor Huggins: '... more than half the male population over the age of 50 suffer from benign tumours of the prostate'. This alone should make this book essential reading for the majority of our profession.

DAVID WALLACE

Management of Surgical Complications, 3rd Edition

Edited by Curtis P. Artz, *Medical University of South Carolina,* and James D. Hardy, *University of Mississippi School of Medicine,*

Prevention is better than cure, so the expert contributors to this widely used work advise on the steps that might be taken to avoid complications—as well as offering plenty of helpful information if they do set in.

Approx 865pp (315 illus) Price £16.65 Hardback binding April 1975

Atlas of Vaginal Surgery

By Professor Gunther Reiffenstuhl, *Frauenklinik, Salzburg, Austria, and* Dr Werner Platzer, *Anatomischen Instituts der Universitat, Innsbruck, Austria.* Edited by Emanuel A. Friedman, *MD, Med. ScD., Beth Israel Hospital, Boston.*

A magnificent, two-part, atlas of gynaecologic surgery. The first section—*Anatomical Description*—by Platzer comprises 70 text pages and 42 drawings; the second—*Operative Technique*—by Reiffenstuhl has 300 pages of text and 330 illustrations.

Approx 600pp (370 illus—full colour throughout) Price £55.55 July 1975

Physical Examination of the Surgical Patient, 4th Edition

An Introduction to Clinical Surgery

By J. Engelbert Dunphy, *MD, University of California School of Medicine,* and Thomas W. Botsford, *MD, Harvard Medical School.*

This 4th edition of a best-selling text includes major changes in the elective examination of the heart, breast, abdomen, and the cancer patient; and the emergency examination of the chest and abdomen and the thermally injured patient.

Approx 430pp (215 illus, 2 in colour) Price £8.85 Hardback binding April 1975

For an inspection copy of these valuable texts write to Colin Dann, Publicity Manager, at 120 Golden Lane, London EC1Y 0TU, quoting ref. WBS 6.

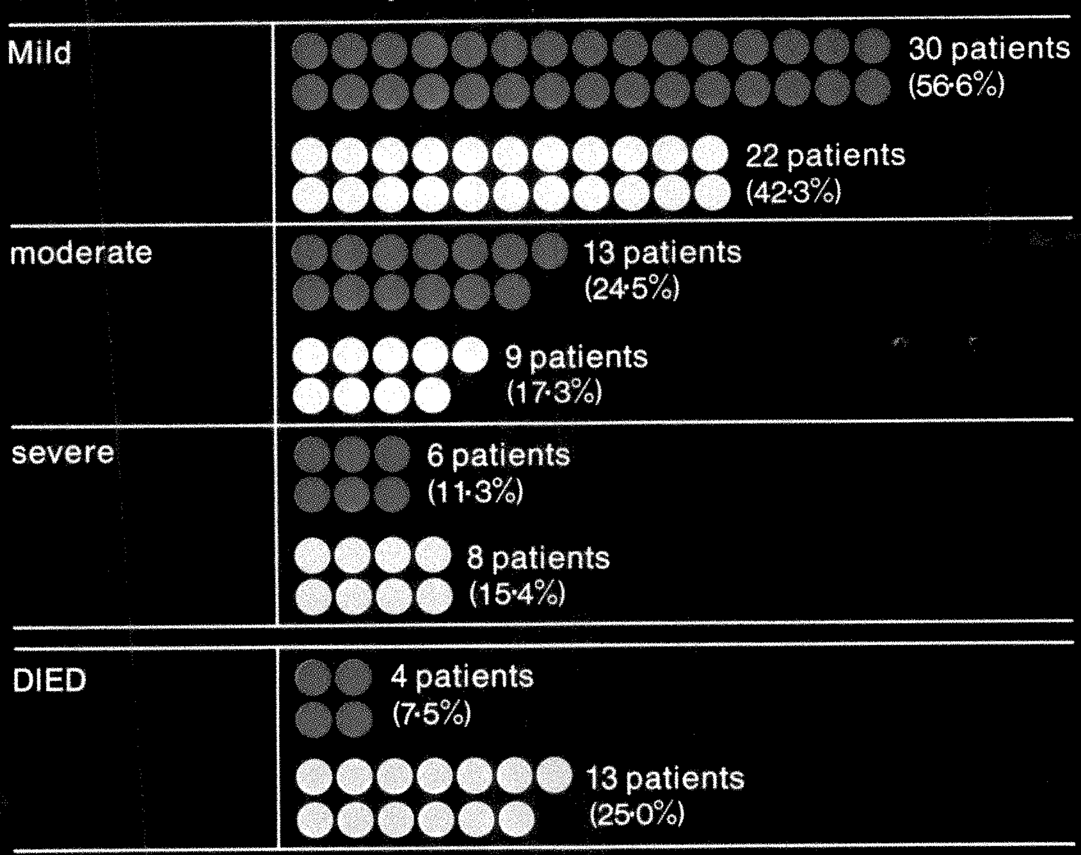
The new evidence for Trasylol in the treatment of acute pancreatitis

Prospective double-blind trial in 105 patients over a five year period shows Trasylol to significantly reduce mortality and morbidity in acute pancreatitis.[1]



● Trasylol group (53)
○ placebo group (52)

'Trasylol must therefore be regarded as a drug which is beneficial in the treatment of acute pancreatitis.'[1]

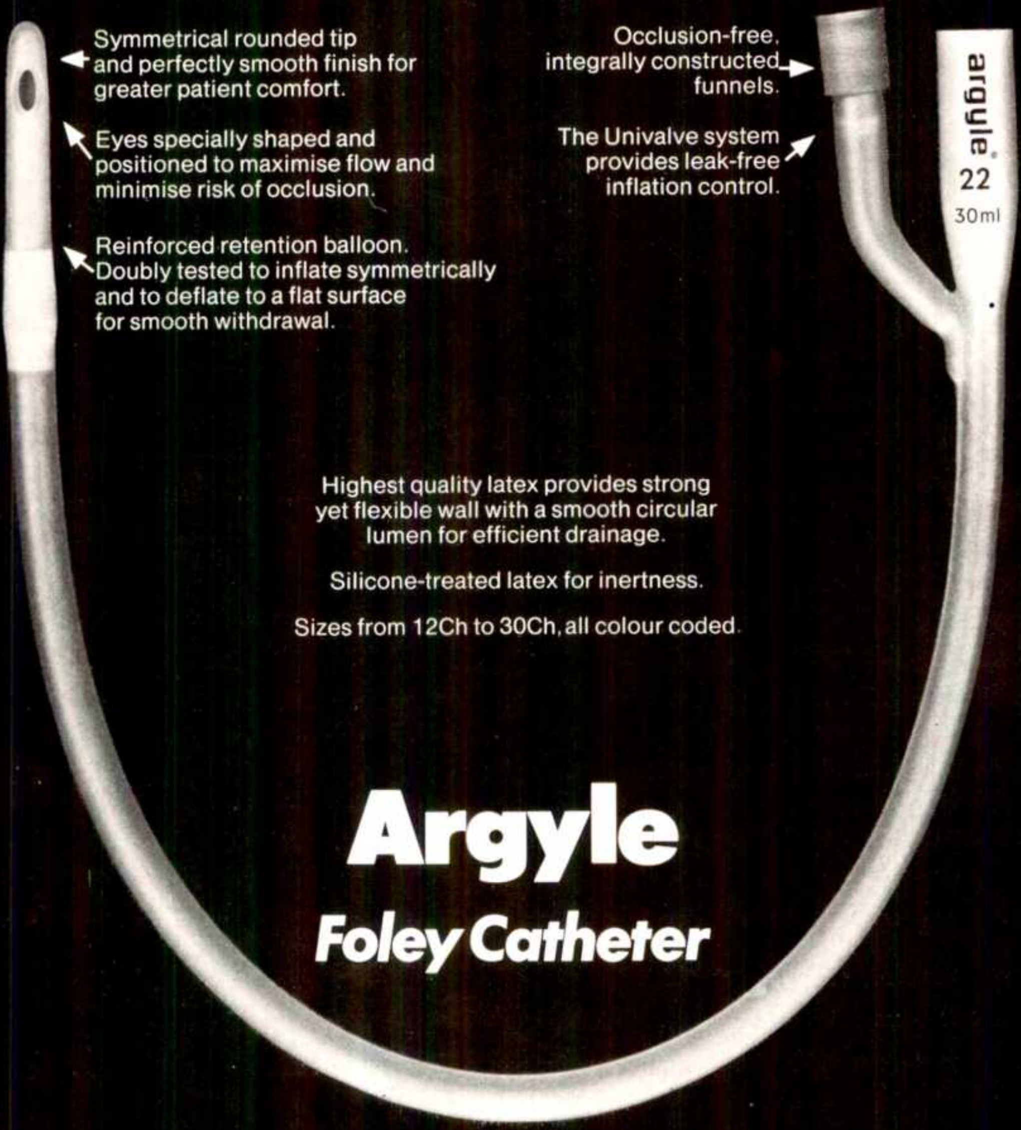
for Foley read Argyle

Read why the Argyle Foley Catheter is simpler, safer, surer than any other Foley catheter



Symmetrical rounded tip and perfectly smooth finish for greater patient comfort.

Eyes specially shaped and positioned to maximise flow and minimise risk of occlusion.

Reinforced retention balloon. Doubly tested to inflate symmetrically and to deflate to a flat surface for smooth withdrawal.

Occlusion-free, integrally constructed funnels.

The Univalve system provides leak-free inflation control.

Highest quality latex provides strong yet flexible wall with a smooth circular lumen for efficient drainage.

Silicone-treated latex for inertness.

Sizes from 12Ch to 30Ch, all colour coded.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

PRESENTATION OF STATISTICS

Authors are reminded that with the frequent use of statistical analysis in biological writing of all kinds it is desirable that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinical trials the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached.

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

Forthcoming Titles

AUGUST

Disaster Planning

Proceedings of a Symposium held at the Royal Naval Hospital, Haslar, Gosport, Hants.

Edited by Surgeon Commander J. W. RICHARDSON, OBE, FRCS, RN, *Consultant Surgeon, RN Hospital, Haslar.*

These papers, which have been presented by those people recognized as experts in their particular field, discuss many contentious points which underline the need for an agreed policy regarding the management of casualties arising from disaster situations. This book is a 'must' for all those concerned with the formulation of disaster plans: police, fire service, ambulance, doctors (accident surgeons, pathologists), hospital staff, voluntary service, coroners, the media. Those concerned with running nuclear power, industry, the railways, aircraft and ships and the sea.

144 pages　19 illustrations　paper covers　£5·00 net.

SEPTEMBER

Chest Injuries

G. KEEN, MS, FRCS, *Thoracic and Cardiac Surgeon, United Bristol Hospitals and Frenchay Group of Hospitals, Clinical Lecturer in Thoracic Surgery, University of Bristol.*

There are many pitfalls of diagnosis and treatment in chest injury that are responsible for avoidable complications and deaths. The book is based on the author's own experience. It will be useful to general surgeons, accident surgeons and anaesthetists and it will also be a practical guide for those who find themselves dealing with a case that is outside their experience.

192 pages　78 illustrations　about £8·00 net.

JOHN WRIGHT

42–44 Triangle West, Bristol BS8 1EX

ARMOUR TEMPORARY BIOLOGICAL DRESSING CAN SOLVE THE IMMEDIATE PROBLEM OF TISSUE LOSS COVERAGE AND REPAIR

effective in the treatment of

- partial thickness burns
- debrided full thickness burns
- traumatic skin loss injuries
- soft tissue defects
- decubitus and vascular ulcers

The many advantages of using a biological dressing are

- dramatic reduction of pain
- reduction of fluid and protein loss
- reduction of heat and energy loss
- reduction of infection
- increase in mobility
- protection of exposed tendons, vessels and nerves
- promotion of healing
- psychological improvement of the patient
- improvement of scarring
- In full thickness burns, used as a "test material" to predict the readiness of the granulating bed to accept autograft. This results in a more economical use of autograft material.

Armour porcine skin dressings are presented in sterile lyophilised form, can be conveniently stored without refrigeration and may be reconstituted prior to use in sterile water or balanced electrolyte solution.

Package and size availability is as follows:
Boxes of 5 x 1 sq. ft. roll 3"x 48"
Boxes of 5 x ¼ sq. ft. roll 3"x 12"
Boxes of 10 Patches 2½"x 4"
Boxes of 5 x Wide Strip 8"x 18"
Boxes of 5 x Wide Half Strip 8"x 10"

The LOR-1A
APPARATUS

CHRONIC TONSILLITIS

successfully treated by
ultrasonic therapy

The LOR-1A apparatus produces mechanical vibrations of ultrasonic frequency which have a therapeutic effect on infected tonsils. Clinical tests have shown 75% success in patients treated. Advantages of the LOR-1A are its small dimensions and low weight (less than 5 kg and its proven safety, reliability and ease of operation. Small ultrasonic generator of loss operating voltage permits direct treatment to tonsils.

The first word in ostomy management

Skin care after ileostomy, colostomy or ileal conduit starts at the time of surgery itself. Stomahesive protects peristomal skin making the patient comfortable and more confident about his future.

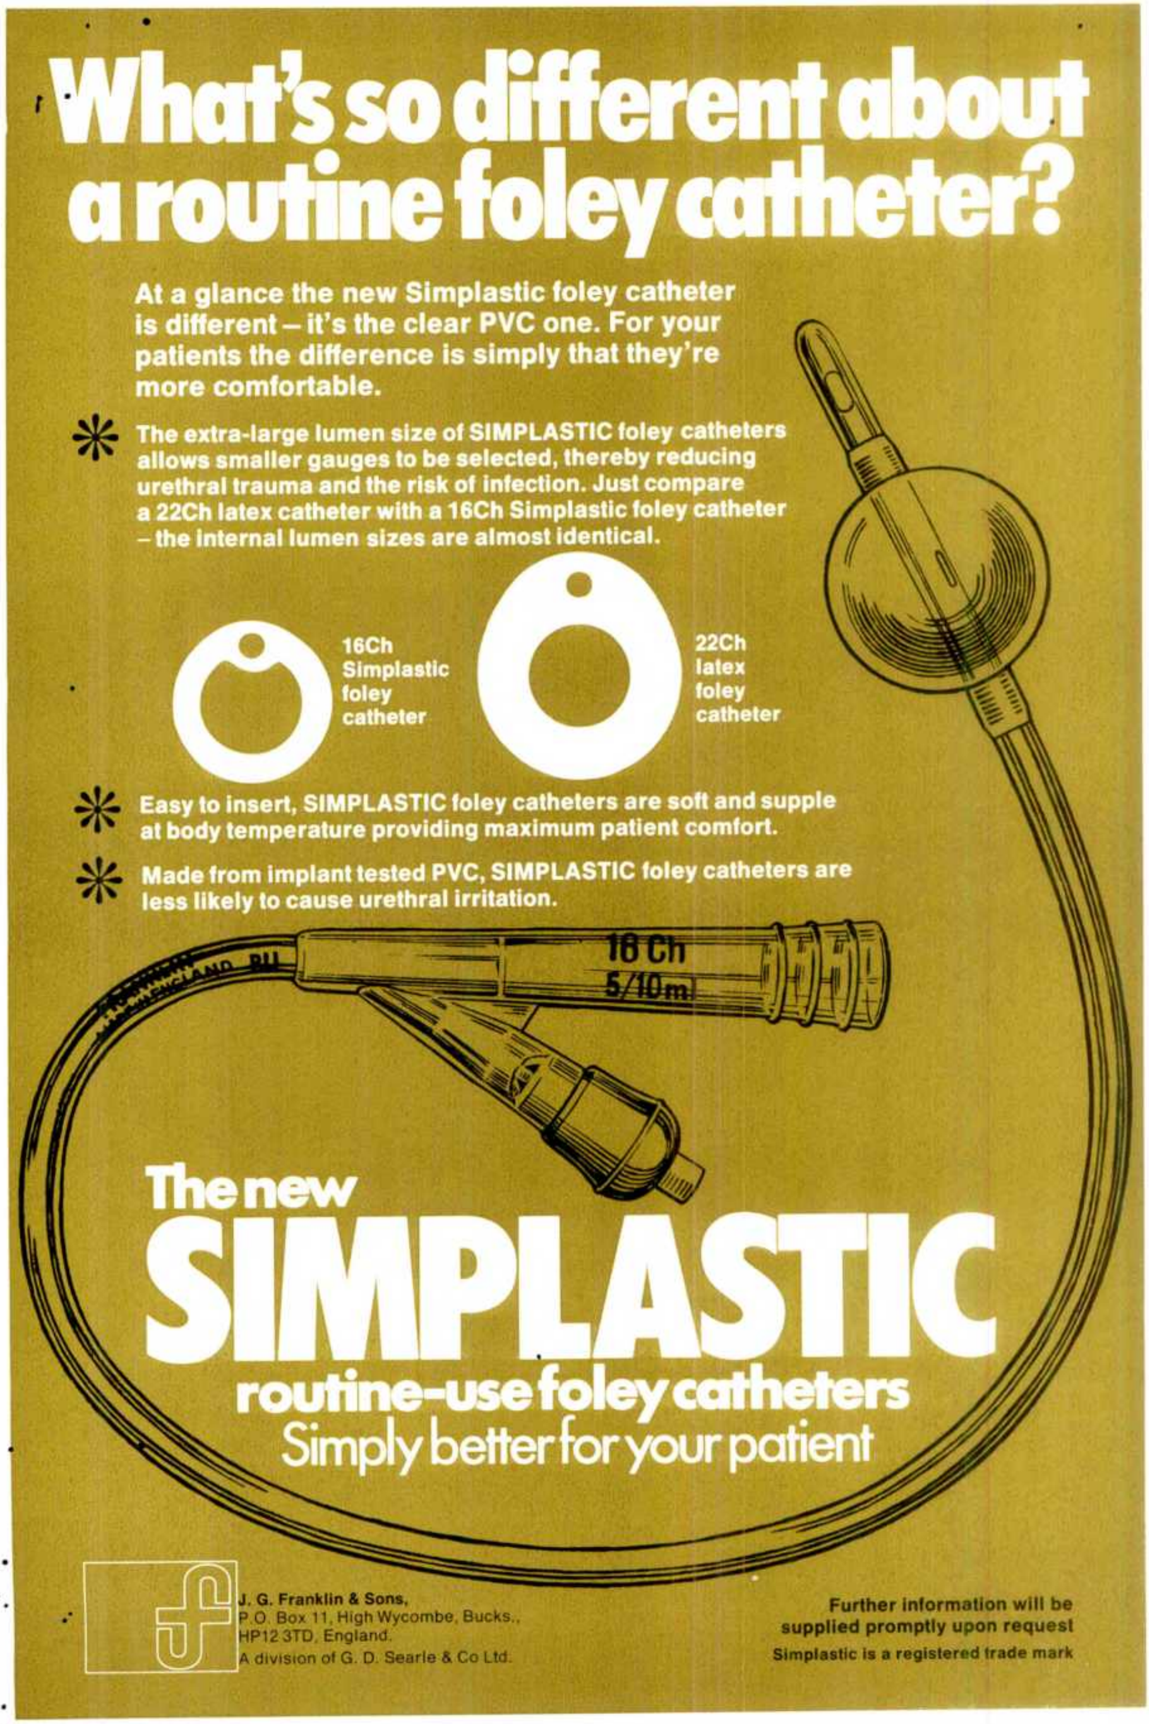
Because Stomahesive contains non-sensitising ingredients, it can be used even on broken, excoriated skin. But why wait for trouble?

Use Stomahesive - right from the start.

Stomahesive, available in boxes of 5 10cm × 10cm squares.

Stomahesive is a Squibb registered trademark. Full information available on request to E.R. Squibb and Sons Limited, Regal House, Twickenham TW1 3QT.

SQUIBB



What's so different about a routine foley catheter?

At a glance the new Simplastic foley catheter is different – it's the clear PVC one. For your patients the difference is simply that they're more comfortable.

✻ The extra-large lumen size of SIMPLASTIC foley catheters allows smaller gauges to be selected, thereby reducing urethral trauma and the risk of infection. Just compare a 22Ch latex catheter with a 16Ch Simplastic foley catheter – the internal lumen sizes are almost identical.

✻ Easy to insert, SIMPLASTIC foley catheters are soft and supple at body temperature providing maximum patient comfort.

✻ Made from implant tested PVC, SIMPLASTIC foley catheters are less likely to cause urethral irritation.

The new
SIMPLASTIC
routine-use foley catheters
Simply better for your patient

BURNS

Including Thermal Injury

The Journal of the International Society for Burn Injuries

Executive Editor: J. ELLSWORTH LAING, F.R.C.S., Odstock Hospital, Salisbury, Wiltshire

To counter the high mortality and morbidity caused by burn injuries needs the teamwork of a wide range of specialists: treatment of the patient can involve plastic, paediatric and orthopaedic surgeons, biologists, immunologists and bacteriologists, while the rehabilitation of the patient can need the efforts of occupational therapists, physiotherapists, psychiatrists and social workers. This new journal is published to foster the exchange of information amongst all those engaged in preventing and minimizing the effects of burn injuries. *Burns* is sponsored by the International Society for Burn Injuries, whose aims are to transcend national boundaries in improving the prevention and care of burns by education, research, practical advice and assistance, and the encouragement of co-operation between all countries and specialists.

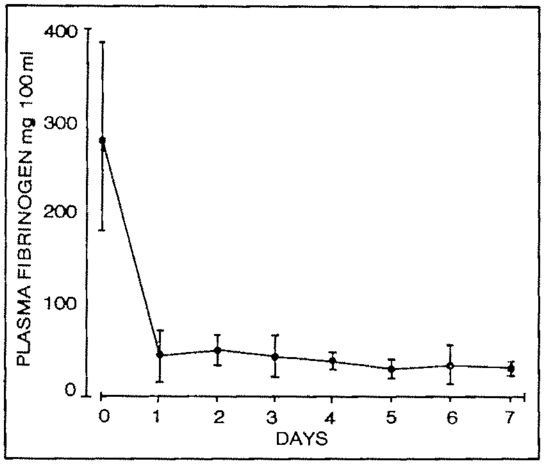
A new concept in the control of occlusive vascular disease.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR, (1971). Thromb Diath Haemorrh, 45, 43.

Its name is Arvin.

This unique drug is now available to specialists, for routine anticoagulant therapy, and to researchers into thromboembolic disorders.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

The consistent does-effect relationship of Arvin allows simple and precise methods of control.

On this basis, we recommend Arvin wherever controlled therapeutic defibrination is desirable.

Full prescribing information, and clinical evidence from studies on the broad range of thromboembolic disorders, are available on request.

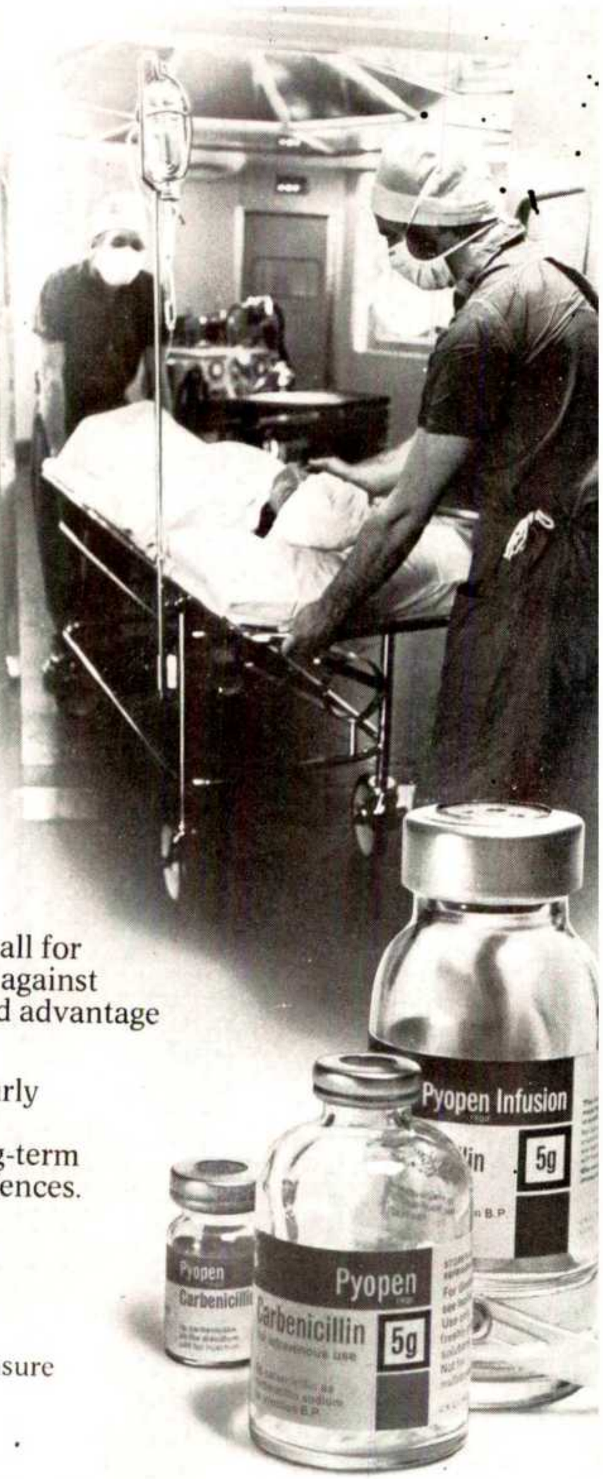
When pseudomonas threatens...



Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . and infection can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen – by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Hepatic resection*

G. B. ONG AND N. W. LEE†

SUMMARY

One hundred and twenty-five hepatic resections were done in the University Surgical Unit at the Queen Mary Hospital, Hong Kong, from 1964 to 1974 for conditions varying from primary hepatoma and recurrent pyogenic cholangitis to spontaneous rupture of the liver due to a bleeding haemangioma.

The overall mortality was 17·6 per cent. A case was classed as an operative death unless the patient was discharged from hospital. There has been long term survival after resection for primary carcinoma of the liver and no mortality when resection was carried out for benign conditions.

IN 1953 we performed a subtotal gastrectomy for a carcinoma of the stomach with resection of the lateral segment of the left lobe of the liver. The patient made an uneventful recovery but subsequently died of metastases 3 years after the initial operation. However, it was not until 1955 that we carried out hepatectomy for primary hepatoma with any frequency at the Kowloon Hospital, Hong Kong. All the records accumulated during the period from 1955 to 1963 were lost, except for those of 1 patient who has been followed up since.

Patients

Over a period of 10 years, from 1964 to 1974, 125 resections of the liver were carried out; one of these, as mentioned, was done at the Kowloon Hospital, the remainder being performed at the Queen Mary Hospital, Hong Kong. There were 83 males and 42 females, giving a sex ratio of 2 : 1.

Table 1: CONDITIONS FOR WHICH LIVER RESECTION WAS CARRIED OUT, 1964–74

	Sex			Age (yr)	
Pathology	M	F	Ratio	Range	Average
Hepatocellular carcinoma	59	11	5 : 1	9½ mth–85 yr	50

Ruptured haemangioma	0	1	0 : 1	—	43

Lesions of the liver requiring resection

Table 1 shows the conditions for which liver resection was carried out.

Primary carcinoma of the liver

There was a total of 70 cases of carcinoma of the liver where resection was possible; of these, 9 were cholangiohepatoma and 61 hepatocellular carcinoma. Of the 61 cases of hepatocellular carcinoma, cirrhosis was present in 35, while among the cases of cholangiohepatoma it was found in 3.

The incidence of hepatocellular carcinoma with cirrhosis of the liver has been reported as 73·1 per cent (Tull, 1932) and 89 per cent (Stewart, 1931). Hou (1958) found that of the 66 per cent of his series with primary liver cancer associated with cirrhosis, 46·5 per cent also had clonorchiasis. Wang and Li (1963) studied 130 resected cases of primary carcinoma of the liver and reported an association of primary cancer with cirrhosis in all except 2 cases. This is of importance as the cirrhotic liver does not take kindly to resection, for even when the liver is mildly cirrhotic but the resection extensive the patient often succumbs to liver failure. Lin (1966) stated that when the liver is cirrhotic, right or left hepatectomy is contraindicated. While it is true that massive resection in a cirrhotic liver often ends in liver failure, at times the resected liver is found to have very little functioning tissue. Hence, a hepatectomy in such cases is still compatible with survival.

Eighteen out of the 70 cases were admitted because the hepatoma had ruptured. The mechanism of rupture has been previously discussed (Ong et al., 1965; Ong and Taw, 1972).

As a result of cirrhosis a number of patients developed portal hypertension, and the resulting bleeding could have been the cause of death in the postoperative period.

Recurrent pyogenic cholangitis

Some cases with recurrent pyogenic cholangitis require resection of the liver. In the present series it was done for intrahepatic stones which most frequently formed in the lateral segment of the left lobe. The bile ducts were thickened, dilated and contained infected bile with stones (*Fig.* 1). The liver parenchyma showed degeneration and was often shrunken to such an extent that it was almost a fibrotic bag. There was usually a stricture at the junction between the medial and the lateral segments of the left lobe and this was possibly the cause of stone formation in the liver. As the bile was invariably infected, resection of the liver often resulted in subphrenic abscess or biliary fistula and occasionally septicaemia. Altogether 38 such cases were subjected to resection of the liver.

Trauma to the liver

Although the incidence of trauma to the liver is increasing owing to more road traffic accidents, the number of cases that require resection is relatively small. In the 10 years of this study there were only 4 cases in which it was necessary to remove a lobe of the liver. In 2 of them the right lobe of the liver had a stellate fracture which compromised the blood supply so that it was necessary to remove this lobe. In 1 patient the right lobe had a linear fracture which was repaired, while the lateral segment of the left lobe was removed. In the remaining patient the fracture was over the medial segment of the left lobe and it was necessary to perform a resection because of necrosis. These patients were relatively young when compared with the patients with other conditions necessitating hepatectomy.

Cysts

There were 2 patients with a cyst in the left lobe of the liver; both patients were elderly females. The cysts were simple and did not contain any malignant tumour.

Liver abscess

During the last 5 years of the study 4 cases of liver abscess were seen. In 1 case an extended right hepatectomy was carried out because the abscess was mistaken for a carcinoma of the liver. On examination, the resected liver contained hardly any normal liver tissue (*Fig.* 2). In another case a right hemihepatectomy was carried out because of haemorrhage into the abscess. Both of these cases were subsequently proved to be amoebic liver abscesses. In addition to these cases there were 2 cases of liver abscess which had initially been drained and subsequently developed a discharging sinus. No amoebae were demonstrated either in the pus or in the wall of the abscess in these cases. Culture was originally sterile, but after drainage pyogenic bacteria were isolated. These were probably the cause of the discharging sinus (*Fig.* 3).

Carcinoma of the colon with metastases to the liver

There were 3 cases in this group; 2 females and 1 male. The male and 1 female patients had a carcinoma of the hepatic flexure which had invaded the right lobe of the liver; the rest of the liver was normal (*Fig. 4*). The third patient had a carcinoma of the sigmoid colon with metastases to the medial segment of the left lobe. The liver was also cirrhotic.

Carcinoma of the bile ducts

There were 2 cases of carcinoma of the right hepatic duct. The patients were markedly jaundiced; the liver was not cirrhotic but was deeply stained. Both were males, one aged 47 and the other 58. Histologically, the tumours were shown to be adenocarcinoma arising from the right hepatic duct.

Leiomyosarcoma of the jejunum

In 1 case a leiomyosarcoma of the jejunum was found with secondaries in the right lobe of the liver. The rest of the liver was normal.

Bleeding haemangioma

A case of bleeding haemangioma was seen in this series. A huge cavernous haemangioma arising from the right lobe of the liver and extending to the medial segment of the left lobe occurred in a female patient. The rest of the liver was normal. The left lobe was rather hypertrophic and the cut section of the resected specimen showed there were some fibro-fatty tissues at the centre (*Fig.* 5).

Clinical features

Abdominal mass

This was by far the most common finding in the patients undergoing liver resection. It was present in all the patients with primary carcinoma of the liver, and in addition the 4 cases of liver abscess also had a mass palpable in the upper part of the abdomen. The patients with a cyst presented with a mass in the upper abdomen which moved with respiration and was non-tender. In carcinoma of the bile duct the palpable mass in the upper quadrant could be identified as a uniformly enlarged liver. The patient with secondary leiomyosarcoma also had an enlarged liver with irregular masses studded over it.

Abdominal pain

Abdominal pain was a constant finding and was usually confined to the right upper quadrant, occasionally radiating to the back or referred to the shoulders. This was present in the majority of the patients with carcinoma of the liver and in the patient with a ruptured haemangioma. The pain was rather sudden and was described as 'bursting' in nature in all cases of ruptured hepatic tumour. Sometimes it was associated with the rapid onset of shock.

Intraperitoneal haemorrhage

This occurred in 18 cases of ruptured carcinoma of the liver. Traumatic rupture of the liver produced intraperitoneal haemorrhage with very severe pain and the patient rapidly went into shock. The amount of fluid varied. In primary hepatoma ascites might be present; and any bleeding, even if severe, would yield only heavily bloodstained fluid on paracentesis.

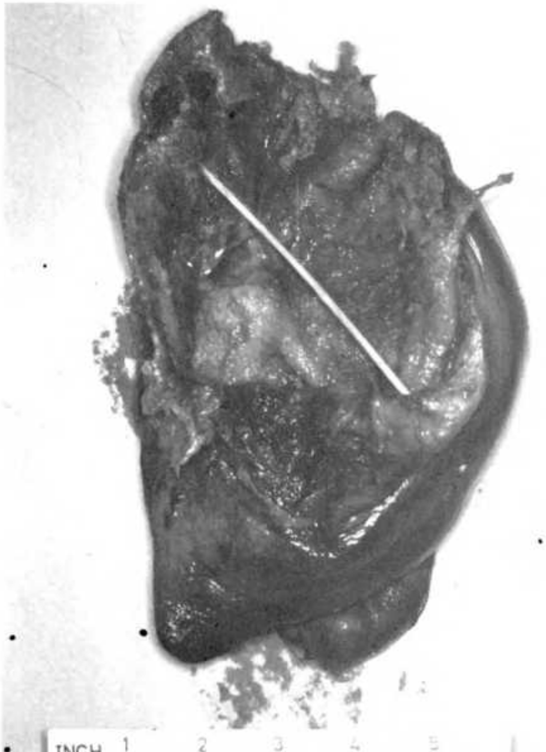

Fig. 2. Specimen of destroyed liver due to amoebiasis. There is hardly any normal liver tissue.

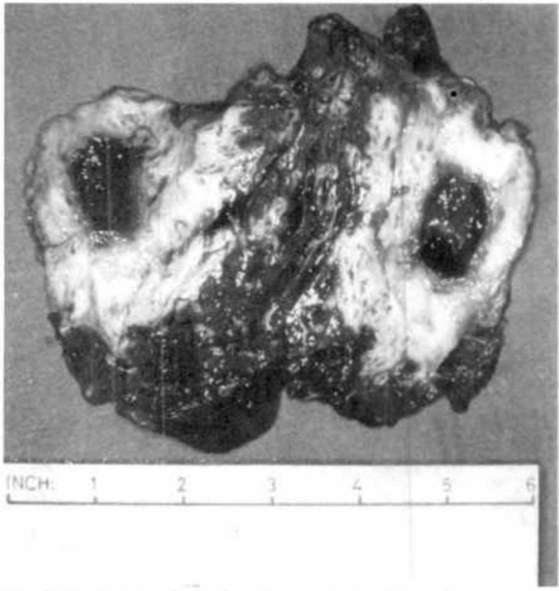

Fig. 3. Persistent sinus after drainage of a liver abscess which was treated and cured by resection.

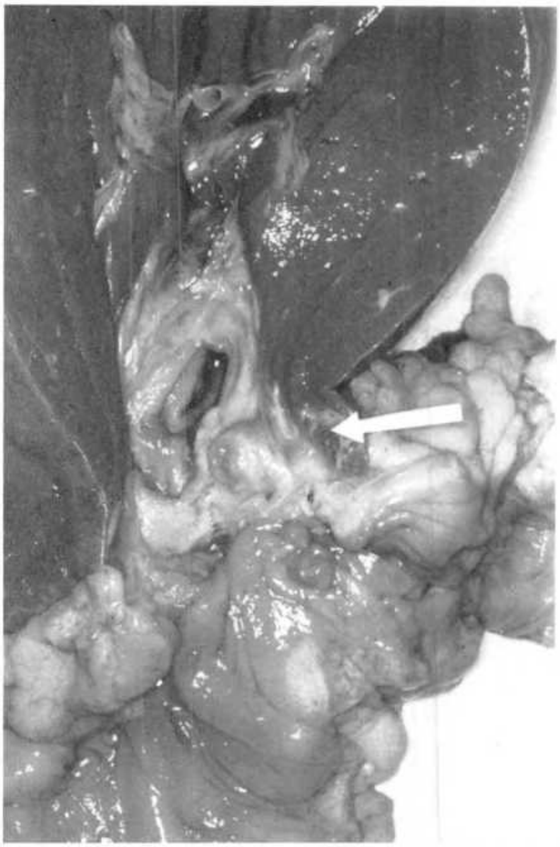

Fig. 4. Carcinoma of the hepatic flexure invading the right lobe of a liver. This was treated by right hepatectomy and right hemicolectomy.

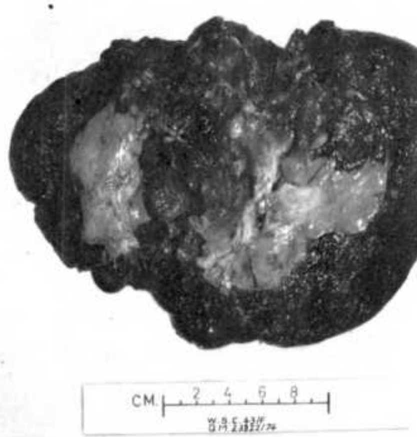

Fig. 5. Bleeding haemangioma of the liver.

Weight loss

Weight loss was found in 37 of the 70 cases of primary hepatoma. It was not found in recurrent pyogenic cholangitis, traumatic rupture, cysts or in the case of a ruptured haemangioma. A variable degree of weight loss was noticed in carcinoma of the colon with liver secondaries, while the patient with carcinoma of the bile duct had marked loss of weight. The patient with leiomyosarcoma of the jejunum had also lost weight.

Anorexia

Approximately half the patients with primary hepatoma complained of anorexia. It was also present in the patients with recurrent pyogenic cholangitis, liver abscess and other malignancy, but was absent in these with traumatic rupture of the liver, cyst and ruptured haemangioma.

Preoperative investigations

Except for emergency operations for bleeding, all the cases were subjected to laboratory investigations.

Laboratory findings

Anaemia was present, although of a mild degree, in all the cases of primary hepatoma. Polycythaemia in primary hepatoma, as reported by McFadzean et al. (1958), was not present in any of these patients. Leucocytosis was also an occasional finding in primary hepatoma and was noticeably absent in the 4 cases of liver abscess, while the white cell count was moderately raised in all the cases of recurrent pyogenic cholangitis. α-Fetal protein gave positive results in 70 per cent of the cases of hepatocellular carcinoma. This test was invariably negative in the patients with cholangiohepatoma.

The liver function tests were of little value except in a case of carcinoma of an intrahepatic duct when the bilirubin was markedly raised. The alkaline phosphatase was not helpful except in the case with obstructive jaundice.

X-ray examination

When X-ray examination showed a soft tissue shadow at the upper abdomen a barium meal study occasionally demonstrated displacement of the stomach, indicating a hepatic mass.

Splenovenography

The usefulness of this investigation lies in the fact that the portal vein may be obliterated as a result of tumour invasion. Should the obstruction extend beyond the bifurcation of the portal vein, then surgical treatment is contraindicated. Portal hypertension is also demonstrated by this procedure.

Hepatic arteriography

Hepatic arteriography is useful in differentiating a malignant lesion with new vessels from a benign one, when the vessels are only displaced.

Scanning of the liver

Scanning with ^{99}Tc does not differentiate a malignant tumour from a benign one. When the lesion is small, scanning usually does not demonstrate any filling defect, and then it is necessary to depend on other investigations for diagnosis as a therapeutic guide.

Peritoneoscopy

Peritoneoscopy is a useful means of diagnosing a liver condition requiring a resection. A primary hepatoma as well as secondary tumour can be seen on the surface. Biopsy under direct vision can then be done and a histological diagnosis made of the lesion. In addition, it is useful in demonstrating the cirrhotic state of the liver. However, peritoneoscopy has many blind spots. The posterior surface of the liver is obscured by adhesions. Any centrally situated lesion will be out of the field of vision.

Inferior vena cavogram

An inferior vena cavogram may occasionally be useful, especially in carcinoma when the tumour has invaded the inferior vena cava, in which case resection is contraindicated.

Preoperative preparations

In most of the cases undergoing elective operation the nutrition should be maintained, and intravenous hyperalimentation will help in getting the patient fit for a major operation. A diet rich in vitamins should be given. Supplementary vitamin A in liquid solution with 10 000 units of vitamin B should be given daily, to which 500 mg of vitamin C may be added. When the prothrombin time is prolonged vitamin K 50/100 mg may be given by intramuscular injection. A diet rich in protein with a high carbohydrate and moderate fat content should be given. Anaemia should be corrected by blood transfusion.

Contraindications to operation

Operative treatment is contraindicated under the following circumstances:

1. *Metastatic spread*: When metastases are demonstrated in the lungs or the bones, surgical exploration should not be carried out. When there are secondaries in the supraclavicular lymph nodes, particularly in

cholangiohepatoma or carcinoma of the colon, operative treatment is out of the question.

2. *Jaundice*: The presence of jaundice is not a contraindication to operation, but may be a contraindication to resection of the liver. Occasionally an hepatocellular carcinoma will spread into the common hepatic duct and produce obstructive jaundice. In such cases resection is not compatible with a cure.

S. A. T., a male patient aged 53 years, was admitted in 1969 because of obstructive jaundice. An operation was performed on 14 July 1969 when a right extended hepatectomy was carried out. He survived 5 months before dying of multiple secondaries in the remnant of the liver (*Fig. 6*).

3. *Ascites*: The presence of ascites is a contraindication to operation, as it indicates that the liver is failing and will not tolerate any operative procedure.

4. *Biochemical changes*: Biochemical changes showing poor liver function indicate that the patients, particularly those with primary hepatoma, with cephalin flocculation of over 3 units, bromsulphthalein retention of over 35 per cent and serum albumin below 2·5 g per cent or prothrombin time below 60 per cent, are unlikely to survive an operation and hence surgery should not be done.

Operations currently practised

Left medial segmental resection

This is an operation that is seldom carried out. It was done only twice in this series; once for trauma to the liver in which the medial segment was completely necrotic and bleeding. It was also done for a ruptured carcinomatous nodule situated in the medial segment of the left lobe. This man subsequently died of bleeding varices. The artery, portal veins and segmental duct were dissected out; these were found half an inch deep to the insertion of the ligamentum teres. The segment was then resected from in front backwards until the medial segmental hepatic vein was exposed and ligated. The segment was removed and the edges of the liver remnant were brought together.

Left lateral segmental resection

In performing left lateral segmental resection the left coronary ligament was freed from the undersurface of the diaphragm. The free end of the coronary ligament contained a few small vessels and in a cirrhotic liver bled profusely. The raw area left on the diaphragm had to be sutured with atraumatic catgut.

After the left lateral segment had been freed, the forceps holding its tip were depressed to expose the lateral segmental hepatic vein. A little dissection freed it from the inferior vena cava. Often the medial segmental vein joined it before they became a single vein draining into the inferior vena cava.

In order to ligate the lateral segmental vein it was occasionally necessary to dissect into the substance of the liver. After its ligature and division, the liver containing the tumour or stone was rotated forwards so that the lateral segment of the left lobe was brought out of the abdomen. The segmental hepatic artery, the segmental duct and the segmental branch of the portal vein were ligated as they ran near the posterior border of the left lobe of the liver. After ligating the artery, vein and the duct, the lateral segment of the liver was ready for division. Further haemostasis of the transhepatic segmental hepatic veins could be attained by suture ligatures.

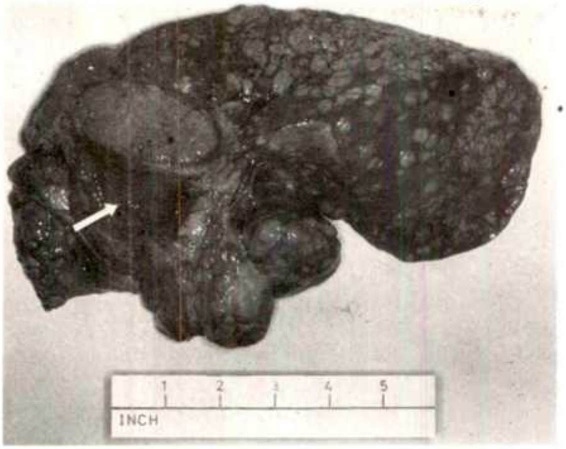

Fig. 6. Secondaries which appeared in the remnant of a hypertrophic liver. Arrow points at the hepaticojejunostomy.

Left hemihepatectomy

In this operation the liver was divided along the principal plane dividing the right and left lobes of the liver. A Mayo-Robson incision was made and the left coronary ligament was divided and detached. The left hepatic vein was dissected out, divided between clamps and stitched as for lateral segmental resection. After division of the left branch of the portal vein, hepatic artery and hepatic duct, the left lobe of the liver became a dusky colour or sometimes even black. The division of this lobe of the liver was now made by cutting through the capsule of the liver and, with the handle of the scalpel, the intersegmental veins were teased out and ligated or stitched. The cut edge of the liver was either sutured with a series of interrupted or continuous catgut sutures, or, in most cases, after controlling the bleeding from the raw surface a piece of Surgicel was placed over it and then pieces of Gelfoam to cover the whole raw area. The Gelfoam was stitched to the capsule of the liver. This method resulted in good healing.

Right hemihepatectomy

Exploration of the back of the liver was first carried out. This avoids division of the structures at the porta hepatis which makes it necessary to resect the devascularized liver. If the tumour has infiltrated the inferior vena cava, resection will result in either part of the tumour being left behind or the inferior vena cava being torn beyond repair.

After exploration, attention was focused on the structures at the porta hepatis. Division and ligation of these structures were performed. Next, the hepatic vein was dealt with.

If the coronary ligament had been freed when the hepatic veins were explored, the liver could be

TABLE II: COMPLICATIONS IN 125 LIVER RESECTIONS

Complication	No. of cases	%
Haemorrhage	4	3
Biliary fistula	11	9
Infection		
Septicaemia	6	5
Subphrenic abscess	13	10·4
Liver abscess	1	0·8
Pleural effusion	4	3

delivered out into the wound. In so doing, there would be a kink of the inferior vena cava. Lin (1966) believed that the kinking of the inferior vena cava would impede the venous return and could cause cardiac arrest. Hence he devised his finger-fracture technique so that the hepatic veins could be divided within the liver substance. Division and removal of the liver were then carried out in the same manner as for left hemihepatectomy. However, kinking of the inferior vena cava can be lessened if the lower hepatic veins are dissected out first and ligatured. This can be done with the liver in the abdomen, and leaves the uppermost hepatic vein which is short and can be found at the bare area of the liver.

In dividing the uppermost hepatic vein over the kink of the inferior vena cava a piece of the inferior vena caval wall might inadvertently be included. If this occurred a transfixion of the vein would inevitably cause the suture ligature to slip and severe bleeding might take place. It is therefore wise, at this stage, to have ready a vascular clamp of the Satinsky type. Should such an accident happen the inferior vena cava could be clamped and sutured.

Extended right hepatectomy

Occasionally, a tumour is large enough to require removal of the liver to the right of the falciform ligament. The exploration and method of dealing with the hepatic veins were similar to those for right hemihepatectomy. The ligature of structures at the porta hepatis was similarly carried out. However, the left medial segmental artery and the right segmental portal vein with the segmental duct have to be dealt with in this procedure. The lateral segmental duct, artery and portal vein were preserved and found to be half an inch deep to the ligamentum teres. At this stage of the division of the medial segmental duct it would be prudent to place a T-tube into the left hepatic duct, for it would prevent damage to the lateral segmental duct.

The raw surface of the liver was again dealt with either by suturing the capsule together or by placing some haemostatic agents and stitching them to the capsule of the liver. If the falciform ligament is not involved it provides a convenient piece of material to stitch over the raw surface.

Extended right hepatectomy represented a removal of between 75 and 80 per cent of the liver tissue, while a right hemihepatectomy removed between 55 and 60 per cent, and removing the left half of the liver represented 45–50 per cent of liver tissue by weight.

Postoperative care

Patients undergoing liver resection required intensive supportive treatment until the remaining liver had regenerated sufficiently to take care of the metabolic needs of the body. Broad spectrum antibiotics were given to prevent chest infection.

Care of the drain

Whenever the chest was opened an underwater seal drain was inserted and removed on the third or fourth postoperative day. An X-ray of the chest was taken on the day after the operation and repeated after the drain had been removed.

Subsequent pleural effusion would require thoracocentesis. A subdiaphragmatic drain was usually placed in the space formerly occupied by the resected liver. A small amount of serosanguineous fluid was always present, but occasionally there was an excessive amount of ascitic fluid in which case the drain was removed. This would prevent excessive loss of ascitic fluid. The drain occasionally might be blocked by a blood clot and therefore too much reliance must not be placed on its efficiency to demonstrate the presence of bleeding. A large distended abdomen with the patient going into shock would indicate postoperative bleeding and steps should be taken to control it.

Administration of fluids

After blood replacement and administration of fluid, 25 per cent glucose should be given through the inferior vena cava via a cut-down; 200 g of glucose were given daily and adequate vitamins were also administered. Oral feeding can usually be restarted on the second or third postoperative day. A high protein diet should be avoided as it has been shown by Pack and Molander (1960) that too high a protein intake might cause intoxication in a patient with massive resection of the liver.

Complications

These are detailed in *Table II.*

Postoperative haemorrhage

Haemorrhage occurred postoperatively in 4 patients undergoing hepatic resection, all for carcinoma of the liver, and in 1 instance the bleeding was into the pericardium from the upper part of the inferior vena cava. The patient was explored again and subsequently made an uneventful recovery. The other 3 cases had bleeding from the collaterals resulting from portal hypertension in a cirrhotic liver. At the conclusion of the first operation there was no bleeding as every part of the raw surface had been run over with atraumatic catgut. Subsequently, further collaterals which had been missed started bleeding and they were controlled by suturing.

Biliary fistula

Eleven cases (9 per cent) had a biliary fistula. Four patients had undergone resection for carcinoma of the liver and in 1 instance it had been a left hepatectomy in which the duct had been closed with interrupted silk in good approximation. However, a fistula developed. A biopsy taken at the margin showed that carcinomatous cells were still present. In one of these cases after an extended right hepatectomy a T-tube was inserted and the medial segmental duct was carefully closed with interrupted fine silk. Nevertheless, leakage occurred but the fistula healed spontaneously.

Six cases had had resection for recurrent pyogenic cholangitis. In each instance the closure had been performed with interrupted silk. Subsequently, the incidence of biliary fistula was lowered by reverting back to closure with atraumatic catgut and then suturing the liver capsule over it. In 1 case the biliary fistula developed after a right hepatectomy for traumatic rupture of the liver. The fistula healed spontaneously without any further operation.

Infection

Infection accounted for the greatest number of complications in the patients undergoing hepatic resections. There were 6 patients who developed septicaemia, and Gram-negative enteric organisms were cultured from the blood. In 3 of them the hepatectomy was for hepatocellular carcinoma while in the other cases for recurrent pyogenic cholangitis.

Subphrenic abscess occurred in 13 patients (10·4 per cent). The abscesses usually developed following incomplete or inefficient drainage of the space left after resection of the liver. Suction drains were used but even this could not completely prevent the development of subphrenic abscess.

Pleural effusion

Pleural effusion occurred in 4 cases and was confined to cases of right hepatectomy in which the chest had been opened. In 2 of them the effusion kept recurring and malignant cells were found in the pleural fluid. In 1 case a combination of right hepatectomy and pulmonary lobectomy caused pleural effusion of the left pleural cavity. Rupture of the spleen occurred during thoracocentesis.

Operative mortality

After undergoing hepatectomy every patient who did not leave the hospital was considered an operative mortality. Thus, a case might have undergone an operation and then died of liver failure 45 or 60 days after operation. This would still be considered as an operative mortality.

There were 22 deaths out of 125 resections, giving an overall mortality of 17·6 per cent. Of these, 15 had had resection for primary hepatoma; 7 of these 15 died in the first 5 years of the series, that is, from 1964 to 1969, when 22 resections were performed, giving a mortality of 32 per cent. In the succeeding 5 years, from 1969 to 1974, there were 48 resections with 8 deaths, giving a mortality rate of 17 per cent. There is therefore a definite drop in operative mortality. This results not only from improved technique but also from better selection of the best operation for a particular case. The following case report is an example of such selection.

Y. S. K., a female patient, was admitted in 1972 because of an enlarging mass which was found to be a hepatoma involving the right lobe of the liver. An hepatic arteriogram showed that the tumour arose from the upper division of the right lobe (*Fig.* 7). This was confirmed by a splenovenogram (*Fig.* 8). Peritoneoscopy not only revealed the presence of the tumour but also cirrhosis of the liver. A needle biopsy confirmed the diagnosis of hepatocellular carcinoma.

At operation it was decided that the tumour should be removed, sparing the inferior division of the right lobe. Accordingly, the segmental duct, the branch of the hepatic artery and the branch of the portal vein to this division were preserved. The rest of the right lobe was then removed. Examination of the operated specimen showed that the tumour had a narrow rim of normal tissue (*Fig.* 9).

The patient had a postoperative haemorrhage at the site where the superior branch of the hepatic vein drained into the inferior vena cava. This had previously been stitched, but a new tear in the upper part of the inferior vena cava extending into the atrium was found at the second operation. This was sutured and the patient made an uneventful recovery. Subsequently, a hepatic arteriogram showed that this segment was functioning and scanning showed a good-sized segment. This patient has been followed up for the past 2 years and she is quite well without any evidence of recurrence of her disease or metastases (*Fig.* 10).

It is possible that this patient would have died had the whole of her right lobe had been removed. The amount of liver tissue that was functioning and removed at operation was minimal.

Among the 70 resections for primary hepatoma 34 patients had cirrhosis of liver and there were 9 deaths, giving a mortality rate of 26 per cent. The causes of death were liver failure in 5 cases, septicaemia in 2 and hypovolaemic shock following uncontrolled haemorrhage in 2. The remaining portion of a very cirrhotic liver did not appear to be able to regenerate sufficiently to take over the function of the removed segment or lobe. Furthermore, bleeding in cirrhotics, especially from collaterals, was always profuse. Even at the very early stage of resection when the liver was being mobilized, much blood could be lost from these collaterals. The haemorrhage could be controlled by packing and subsequently with running stitches. In an attempt to replace blood loss with massive transfusion, a coagulation defect could develop and this was often the cause of death.

Septicaemia was also much more likely to occur in these patients, for they tolerated infection poorly. Two of the cases dying of septicaemia belonged to the group of patients with recurrent pyogenic cholangitis that required liver resection.

Traumatic rupture of the liver occurred in 2 patients with multiple injuries; both patients died of cardiac arrest following irreversible shock shortly after operation. Although the resections were extensive, the other benign conditions in this series did not give rise to any mortality. None of the patients operated on for carcinoma of the colon with liver metastases died within the postoperative period.

The patient with leiomyosarcoma who died of cardiac failure was known to have cardiac ischaemia.

Two cases of carcinoma of the bile ducts were operated on; one was an extended right hepatectomy and the other a right hepatectomy. Reconstruction of the biliary tract was in each instance by hepatico-jejunostomy. One patient developed a subphrenic

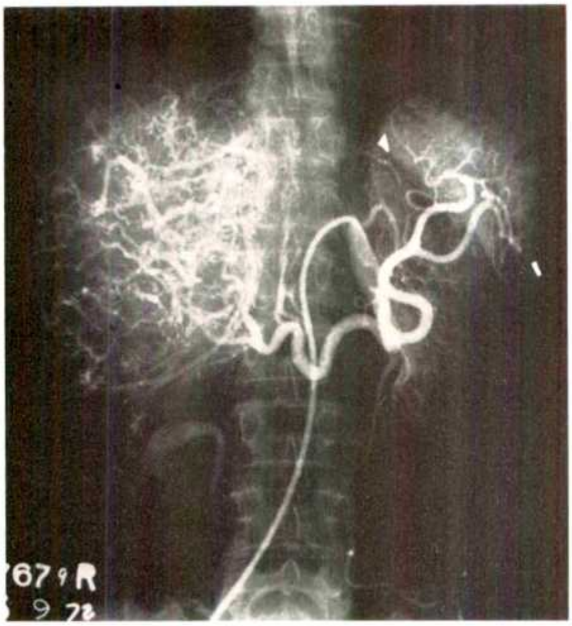

Fig. 7. Hepatic arteriogram in a primary carcinoma of the liver. Note the new vessels entering the tumour. The right inferior division is normal.

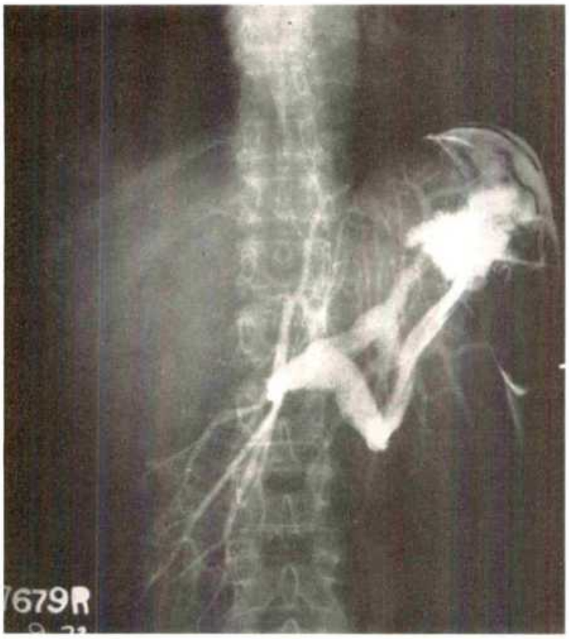

Fig. 8. Splenovenogram showing infiltration of cancer in the segmental vein.

abscess but both died of liver failure. Their jaundice never subsided and their condition deteriorated until they went into coma and died 40 and 48 days after operation respectively.

The survivors

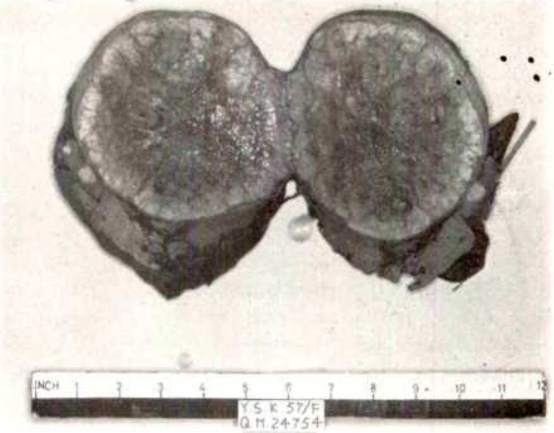

Fig. 9. Resected specimen of a liver showing a large carcinoma.

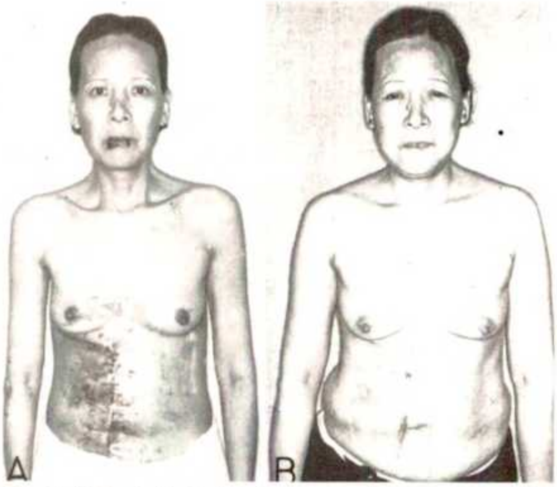

Fig. 10. Patient who had had a primary hepatoma resected; (*A*) during convalescence, and (*B*) 2 years afterwards.

Of the 103 patients who survived hepatic resection, 39 subsequently died from 5 to 41 months after operation, the average being 10 months. All died of their original disease. One patient with recurrent pyogenic cholangitis died 18 months after hepatectomy. She developed leakage of bile through the old drainage wound which was persistent and it was necessary to explore the bile ducts to close this biliary fistula. She died of uncontrolled haemorrhage due to a coagulation defect.

Carcinoma of the colon with metastases to the liver accounted for 2 deaths. One was a female patient who survived a right hepatectomy with the right hemicolectomy carried out in continuity. This patient was operated on in 1968. She survived for 18 months but eventually died of her disease.

Up to the present time 64 cases are still alive out of the original 125. *Table III* shows that 19 of the patients with carcinoma of the liver are alive and the longest survival is now 13 years. This is a patient who had a left hemihepatectomy done in 1962 for a ruptured hepatoma and who emigrated in 1971. The second longest survivor is a man with hepatoma which ruptured while being investigated. An emergency extended right hepatectomy together with partial excision of the diaphragm was carried out. This patient is still alive and well. A female who was operated on for a hepatoma of the left lobe with two secondary nodules on the medial segment is alive and well today, 5 years after the operation. Of the remaining surviving patients, 1 was operated on in 1971, 3 in 1972, 4 in 1973 and 8 in 1974.

Of the patients with other conditions who are still alive after hepatic resection (*Table IV*), one had a carcinoma of the sigmoid colon with metastases to the liver for which a total colectomy and left medial segmental resection was carried out 15 months ago.

Thirty-five of the cases with recurrent pyogenic cholangitis are still alive 6 months to 10 years after operation.

Of the patients with traumatic rupture, one who had a right hemihepatectomy done 7 years ago and another who had a left medial segmental resection performed 3 years ago are alive at the present time.

The 2 patients with a cyst which was treated by left hemihepatectomy have survived without problems for 2 years and 5 years respectively.

Of the patients with liver abscess who were operated on, one had an extended right hepatectomy which was carried out 4 years ago. This was a patient who was operated on because of a mistaken diagnosis of hepatoma arising from the right lobe of the liver. As the lesion was soft it was thought to be a necrotic tumour. No aspiration of the abscess was carried out. He made an uneventful recovery and was discharged from hospital after 2 weeks. He has been followed up since and the liver has regenerated to its original size and he is at the present moment quite well (*Fig.* 11).

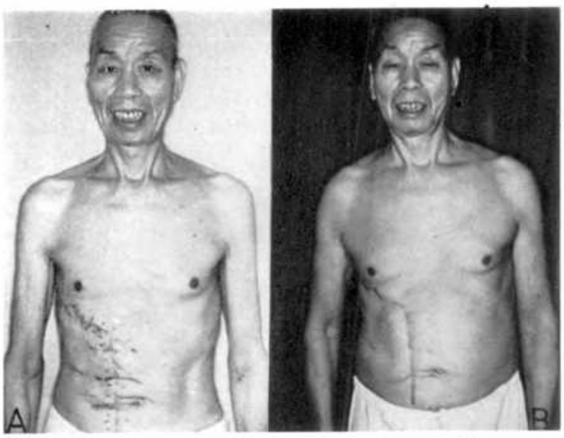

Fig. 11. Patient who had undergone resection of a liver abscess; (*A*) 6 months, and (*B*) 4 years following operation.

The ruptured haemangioma was operated upon on 6 July 1974; the patient was discharged 10 days after the operation.

Discussion

Certain conclusions can be drawn from the present series.

Operative mortality

Primary hepatoma carried the highest operative mortality, which is understandable because hepatoma is a complication of a cirrhotic liver. Islami et al. (1958) have shown that in rats with carbon-tetrachloride-induced cirrhosis the liver remnant after resection could regenerate and function normally. However, in humans when a cirrhotic liver is resected it does not

Table III: DETAILS OF 19 SURVIVING PATIENTS WHO UNDERWENT RESECTION FOR PRIMARY HEPATOMA

Year of operation	Type of resection	Lesion	No. of cases
1962	Left hemihepatectomy	Ruptured hepatoma	1
1966	Extended right hepatectomy	Ruptured hepatoma	1
1969	Left hemihepatectomy	Hepatoma	1
1971	Left hemihepatectomy	Hepatoma with cirrhosis	1
1972	Right or left hemihepatectomy	Hepatoma with mild cirrhosis	3
1973	Right or left hemihepatectomy or extended right hepatectomy	Hepatoma, 2 with and 2 without cirrhosis	4
1974	Right or left hemipatectomy or extended right hepatectomy	Hepatoma with or without cirrhosis	8

Table IV: DETAILS OF SURVIVING PATIENTS WHO UNDERWENT RESECTION FOR CONDITIONS OTHER THAN PRIMARY HEPATOMA

Lesion	Type of resection	No. of cases	Length of survival to date
Carcinoma of sigmoid colon with metastasis to liver	Total colectomy with left medial segmental resection	1	15 mth
Recurrent pyogenic cholangitis	Left lateral segmental resection	35	6 mth–10 yr
Traumatic rupture	Right hemihepatectomy, left medial resection	2	7 and 3 yr
Liver cyst	Left hemihepatectomy	2	2 and 5 yr
Liver abscess	Extended right hepatectomy	1	4–9 yr
	Left hemihepatectomy	2	
	Right hemihepatectomy	1	
Ruptured haemangioma	Right hemihepatectomy	1	10 d

regenerate into a normal functional unit. There may be islands of regeneration. In fact, the hepatoma most probably arises from one of these regenerated nodules.

As hepatocellular carcinomas are always at an advanced stage when first seen, massive resection is often required. If cirrhosis of the liver is severe, massive resection will always end in death from liver failure. However, with proper selection of cases and correct application of operative treatment the mortality rate should be reduced to an acceptable level.

From 1964 to 1969 the operative mortality from hepatic resection for primary hepatoma was 32 per cent. In 1974 there were 9 resections for primary carcinoma of the liver with only 1 death, a mortality of 11 per cent. Lin (1973) reported a mortality rate of 11·9 per cent in a series of resections for primary hepatoma of the liver. Further, he gave a figure of 19·1 per cent for 5-year survival.

Hepatic resection for secondary carcinoma should carry a very low mortality. In 3 resections for metastasis from carcinoma of the colon there was not a single death. When resection is carried out for a benign non-infective condition there should be no mortality, as shown by results for the cysts and the bleeding haemangioma in the present series. However, when the operation is performed for infected bile ducts with intrahepatic stones, then the mortality is 5 per cent.

Technical difficulties

Exposure of the liver has always been found to be difficult. A correct incision gives a good view of the liver which is fixed to the posterior abdominal wall. The incision that we have employed is a right transrectus incision. On exploration if it is found that the right hepatic resection is necessary the upper end of the incision is extended to the right side of the chest, cutting through the costal cartilage without opening the pleura. However, there is no bar to opening the pleura if a better exposure is required. Smith (1968) preferred a right thoraco-abdominal incision as he considered it desirable to open the chest to minimize the likelihood of air being sucked into the hepatic vein during resection and believed that positive pressure could prevent this action. We have not encountered this problem of air embolism.

Control of haemorrhage

Lin (1966) believed that it was extremely difficult to control haemorrhage from the hepatic veins if they were divided first. We have not found any problem in dividing the hepatic veins. The left hepatic duct is found and ligated fairly easily. There are two veins draining each segment of the liver; the right hepatic veins are much more difficult to expose.

Bleeding also occurs from the collaterals between the surface of the liver and the diaphragm. As much as a litre of blood may be lost rapidly when the right coronary ligament is divided. This can first be controlled with packing and subsequently with a continuous running stitch of atraumatic catgut. Bleeding can also occur as a result of a coagulation defect. This should be prevented and adequate fibrinogen given if massive transfusion is needed. Fibrinolysis can take place during or after resection of the liver; hence epsilon aminocaproic acid should be available and used when the blood fails to clot. Bleeding from the intersegmental veins has led many surgeons to use hepatic clamps. We have not found this to be necessary.

The effect of hepatic ischaemia on liver function and the restoration of liver mass after 70 per cent partial hepatectomy in the dog

R. J. MACKENZIE, C. M. FURNIVAL, MAUREEN A. O'KEANE
AND L. H. BLUMGART*

SUMMARY

Partial hepatectomy was performed in dogs either as the only procedure or following a period of ischaemia to the liver remnant produced by inflow occlusion for periods of 30–60 minutes before partial hepatectomy. Temporary portal decompression was maintained through the portion of liver subsequently excised.

1. Survival in dogs subjected to partial hepatectomy and ischaemia to the liver remnant was similar to that in animals after partial hepatectomy alone.

2. Metabolic changes were similar in both groups but dogs submitted to partial hepatectomy and ischaemia to the remnant had higher serum alkaline phosphatase and alanine amino-transferase levels with increased bromsulphthalein retention in the fourth to sixth postoperative weeks.

3. Replacement of liver mass proceeded rapidly in all groups of animals.

It is concluded that ischaemia of the liver remnant for up to 60 minutes preceding partial hepatectomy in the dog is consistent with survival and produces little change in postoperative liver function or in the rate of restoration of liver mass.

MAJOR hepatic resection, performed with increasing frequency for liver injury and liver cancer, is followed by metabolic and haematological changes which appear to be more marked in severely injured hypotensive patients (Vajrabukka et al., 1975). Hypoglycaemia, hypo-albuminaemia, jaundice and bleeding disorders are all known to occur after major liver resection, but the pattern of these disorders in relation to the condition of the liver and the general condition of the patient prior to operation has not been clearly defined.

It is almost impossible in the clinical stiuation to investigate the mechanisms underlying these changes because it is difficult to distinguish the effect of liver resection itself from the effects of preceding liver injury, other injuries and hypovolaemic shock. In order to investigate these problems the metabolic and haematological changes which follow major liver resection have been studied in the dog. In particular, the effect of various periods of normothermic ischaemia of the liver remnant prior to resection in relation to postoperative liver function and restoration of liver mass has been studied. The following report is concerned with the metabolic changes which follow hepatectomy in these circumstances.

Materials and methods

General methods

Experiments were performed on 39 dogs weighing 17·0–33·6 kg (mean 23·8 kg). Each animal was fasted for 18 hours before operation. After premedication with acetylpromazine (Acepromazine, Crookes Veterinary Ltd, 1 mg i.m.), anaesthesia was induced by intravenous sodium pentobarbitone (Intraval Sodium, May & Baker Ltd, 25 mg/kg), an endotracheal tube was passed and anaesthesia maintained with a mixture of nitrous oxide, halothane and oxygen with the animal breathing spontaneously. Catheters were placed in the right femoral artery and in the portal vein via the left gastric vein to record systemic arterial and portal venous blood pressures respectively. Each catheter was connected to a pressure transducer (Devices Instruments Ltd, Type 4-327-L221), and pressures were recorded continuously throughout the operative procedure on a multi-channel recorder (Devices Instruments Ltd, Model MX4). Each pressure-recording system was calibrated before and at intervals during each experiment. During the operation and in the immediate postoperative period, infusions of 0·9 per cent saline solution were given into the cephalic vein to replace blood loss and to maintain fluid balance. Measurements of pH, $Pa\text{CO}_2$ and $Pa\text{O}_2$ were made on samples of femoral arterial blood at intervals during the operation, and metabolic acidosis was corrected by intravenous injection of 8·4 per cent sodium bicarbonate solution.

Partial hepatectomy

Partial hepatectomy was carried out by a modification of the method described by Sigel (1963), in which the left and central portions of the liver are removed, leaving the right lateral and caudate lobes as the liver remnant (*Fig.* 1). Through a midline upper abdominal incision the gastrohepatic omentum is divided and the branches of the bile duct, hepatic artery and portal vein to the left and central parts of the liver are ligated and divided. The left and central hepatic veins are secured between clamps, divided and oversewn. Partial hepatectomy is completed by ligation and division of the papillary process, leaving a minimum of crushed liver tissue, namely a few grammes adjacent to the

ligature around the papillary process. This technique removes 70 ± 5 per cent of the liver substance (Sigel, 1963).

The excised liver was weighed after removing the gallbladder and draining excess blood. After completion of the procedure, the catheter in the femoral artery was removed and the artery repaired, the portal cannula was removed and the left gastric vein tied and the abdominal wound was closed. Six weeks after operation each animal was sacrificed and the liver remnant removed and weighed. Restoration of liver mass was measured by expressing the weight of the liver remnant post mortem as a percentage of the estimated total liver weight prior to resection. Estimated total liver weight was derived from the weight of the liver resected at the partial hepatectomy on the assumption that this represented 70 per cent of the liver mass (Sigel, 1963). Samples of tissue were taken from the liver resected at partial hepatectomy and from the regenerated liver remnant post mortem for histological examination.

Temporary inflow occlusion of liver remnant
In 17 animals, after division of the bile ducts and the branches of the hepatic artery to the central and left lobes, the branches of the portal vein and hepatic artery supplying the liver remnant, i.e. caudate and right lateral lobes, were occluded for periods of 30, 45 or 60 minutes. At the end of each period, after re-establishing inflow to the liver remnant, partial hepatectomy was performed as described above. The efficacy of this complete inflow block was tested by an isotope clearance method, injecting ^{133}Xe (3 µl; 10 µCi/ml) into the substance of the remnant, with a scintillation counter (Rank Precision Industries, Type P 1062) placed over the injection site; activity was recorded using a ratemeter (Nuclear Enterprises, Type 7000 Series) and chart recorder (Servoscribe, Type RE 511.20). Intralobar temperature was recorded from a thermistor probe placed within one of the remaining lobes. During the period of occlusion, portal venous blood drained freely through the lobes of the liver later to be excised.

Liver function tests
Serum bilirubin, alkaline phosphatase, alanine transaminase (SGPT), aspartate transaminase (SGOT), total protein, albumin and bromsulphthalein (BSP) retention were measured daily in the first week after operation and at weekly intervals up to 6 weeks. Blood sugar was measured in the early postoperative phase. The methods used to estimate each of these substances are shown in *Table I.*

Experimental groups
The following groups of experiments were performed:

Group I: Control animals (5 dogs); laparotomy alone (including handling of abdominal viscera), with anaesthesia for a time similar to that in animals undergoing partial hepatectomy.

Group II: Partial hepatectomy alone (17 dogs).

Group III: Partial hepatectomy following a period of total inflow occlusion of the liver remnant for 30–60 minutes with concomitant portal decompression (17 dogs).

Results

General

In the initial experience of hepatectomy 2 animals died as a result of technical error. In subsequent experiments obstructive jaundice followed hepatectomy in 3 animals. In each case this was shown to be due to accidental ligation of the bile duct draining the liver remnant, associated with an anatomical variation in the biliary system. In later experiments animals found to have this variation were excluded from the resection programme and used as controls. During the procedures described in detail below, systemic arterial pressure ranged from 170/115 to 80/55 mm Hg (mean

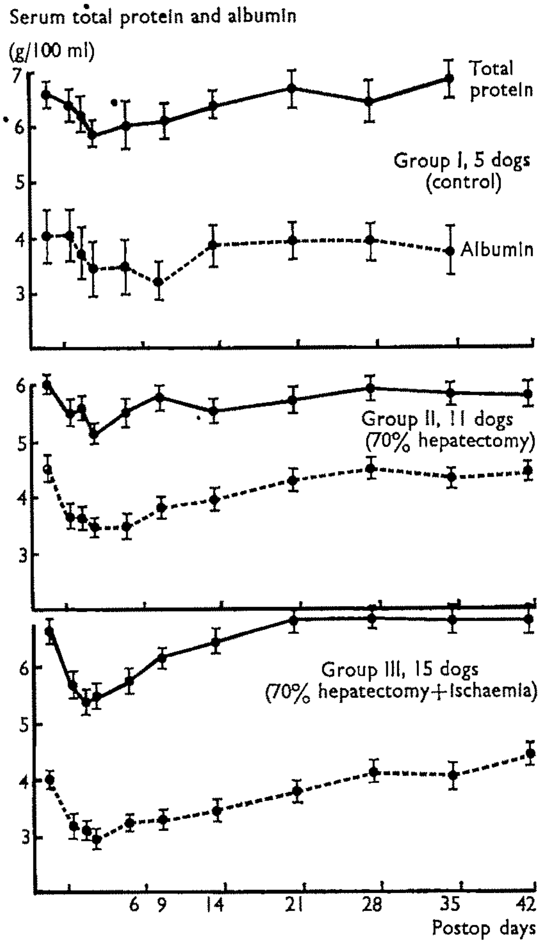

Fig. 5. Total serum protein and serum albumin levels (mean ±1 s.e.) in groups I, II and III.

126/84 mm Hg). Portal venous pressure was 3·4–19·0 cm H_2O (mean 10·4 cm H_2O) prior to resection; following resection, portal venous pressure increased by 1–8 cm H_2O, a mean increase of 3·0 cm H_2O. In all the experiments the initial arterial blood pH was 7·16–7·3 (mean 7·24) and the lowest value during the experiment was 7·08–7·27 (mean 7·23). Arterial blood gases were recorded throughout each experiment; the range of values was for Pa_{O_2} 97–192 mm Hg (mean 149 mm Hg), and for Pa_{CO_2} 37–68 mm Hg (mean 52 mm Hg).

Surviving animals tolerated the procedures well and were ambulant and drinking on the day after operation. They had resumed a full diet by the third postoperative day and maintained their weight. None showed an overt bleeding tendency in the postoperative period nor did hypoglycaemia (i.e. less than 40 mg/100 ml) occur.

Group I

In dogs undergoing laparotomy alone (i.e. control animals) no important change in serum bilirubin was found (*Fig.* 2), and the serum alkaline phosphatase showed a small transient rise with a maximum on the first postoperative day (*Fig.* 3). No important change in SGPT was found, but serum SGOT rose on the first postoperative day to a mean value of 99 mu./ml (range 43–235 mu./ml), returning to normal values before the end of the first week (*Fig.* 4). A reduction in total protein was due to a fall in serum albumin, reaching a minimum value at the end of the first week after operation (mean 34 g/l, range 26–41 g/l); preoperative values were obtained by the end of the second week as shown in *Fig.* 5.

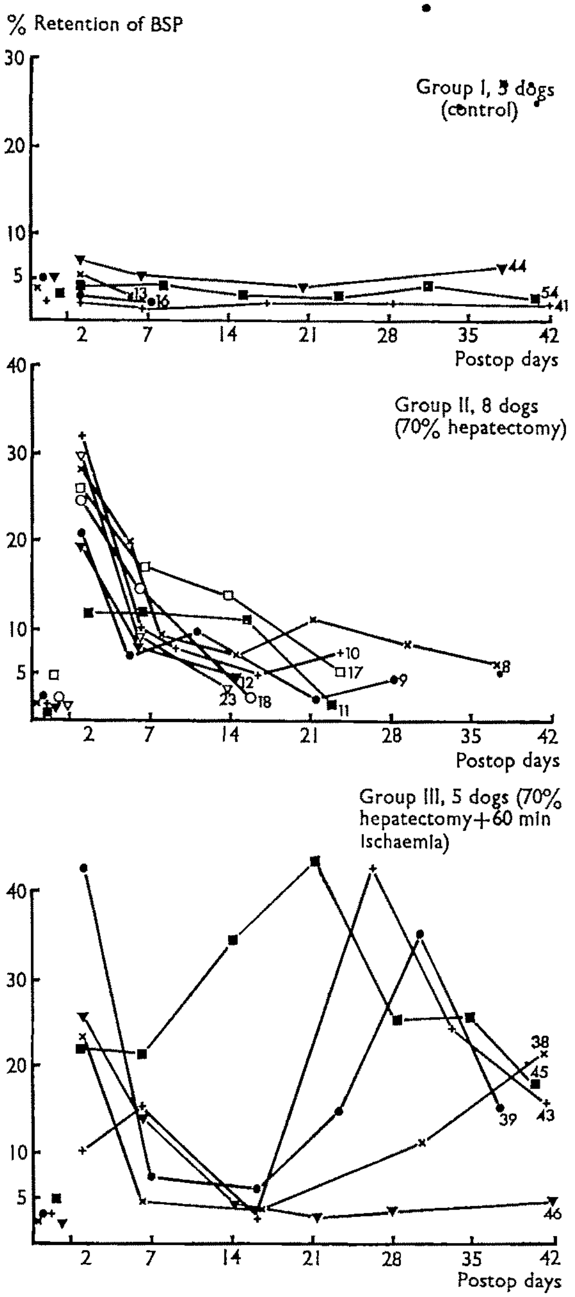

Fig. 6. BSP clearances from animals in groups I and II and after 60 minutes' ischaemia in group III. Each animal's results are shown separately.

On the second postoperative day BSP retention was less than 7·5 per cent at 30 minutes in 5 animals tested (*Fig.* 6).

Group II

Of 17 animals undergoing partial hepatectomy alone, 2 died from technical failure during hepatectomy (*see above*). Of the remaining 15 dogs, 14 (93 per cent) survived for 6 weeks after hepatectomy. The dog which died recovered from anaesthesia but failed to drink and died on the third day after operation. No clear cause of death was established. Of the 14 survivors, 3 developed obstructive jaundice as described above; these were excluded from the analysis, and the biochemical tests described below were performed on the remaining 11 dogs.

Measurements of serum bilirubin in these dogs showed a small transient rise (mean 0·6 mg/100 ml, range 0·27–1·04 mg/100 ml) in the first 3 days after operation; the mean maximum did not exceed the upper limit of normal (*Fig.* 2). Serum alkaline phosphatase showed a much greater rise to a peak (mean 290 u./l, range 100–624 u./l) at the end of the first week. In the remaining 5 weeks the alkaline phosphatase decreased gradually, the mean at 6 weeks being at the upper limit of normal values (mean 70 u./l, range 23–162 u./l), as shown in *Fig.* 3.

Both SGOT and SGPT showed a large early increase after partial hepatectomy (*Fig.* 4). In each case the peak occurred within 48 hours of operation (SGOT mean 300 mu./ml, range 100–627 mu./ml; SGPT mean 220 mu./ml, range 116–342 mu./ml). Both enzymes returned towards normal values which were reached in the case of SGOT by the third week after operation but SGPT remained persistently elevated at 6 weeks (mean 100 mu./ml, range 21–242 mu./ml).

Changes in serum total protein paralleled those of serum albumin (*Fig.* 5), which fell to its lowest value (mean 35 g/l, range 29–38 g/l) in the first week after operation, returning thereafter to preoperative levels in the sixth week (mean 44 g/l, range 38–49 g/l).

Retention of BSP was measured in 8 of the 14 dogs surviving partial hepatectomy alone and showed an early rise to abnormal values on the second postoperative day (mean 25 per cent, range 12–32 per cent). Subsequent measurements showed a return towards preoperative values, retention being less than 10 per cent in all animals by the fourth week after operation (*Fig.* 6).

Restoration of liver mass was measured as described above, and in this group was a mean of 91 per cent (range 76–112 per cent) at the time of sacrifice. Histological examination of liver taken from these animals at post-mortem showed a pattern indistinguishable from that of a normal dog liver.

Group III

Of 17 dogs in which the vascular supply to the liver remnant (caudate and right lateral lobes) was completely occluded for periods of 30–60 minutes (*Table II*), 15 dogs (88 per cent) survived. Neither of the 2 dogs which died regained consciousness after anaesthesia and the cause of death was not established. The period of inflow occlusion in these 2 dogs was 45 and 60 minutes.

Table II: TIME OF OCCLUSION AND SURVIVAL OF ANIMALS IN GROUP III

Time of occlusion (min)	No. of animals	Survivors
30	5	5
45	6	5
60	6	5

Serum bilirubin in this group showed only a small rise (mean 0·6 mg/100 ml, range 0·31–1·04 mg/100 ml) in the first 3 days after operation, and the mean maximum did not exceed the upper limit of normal (*Fig.* 2). Serum alkaline phosphatase was elevated in the immediate postoperative period (mean 130 u./l, range 53–262 u./l), but in some animals continued to rise slowly throughout the period of survival (*Fig.* 3), the highest mean values being recorded 6 weeks after operation (mean 360 u./l, range 49–940 u./l).

There was a large early rise in SGOT and SGPT to a peak about 48 hours after partial hepatectomy (SGOT mean 190 mu./ml, range 80–656 mu./ml; SGPT mean 250 mu./ml, range 85–858 mu./ml). Both enzymes subsequently returned towards normal values (*Fig.* 4), but whereas SGOT was within the normal range 2 weeks after operation, SGPT remained elevated, the mean remaining consistently about 100 mu., and in the fifth and sixth weeks after hepatectomy showed a secondary rise reaching at 6 weeks a peak similar to that found 48 hours after operation (mean 230 mu./ml, range 21–628 mu./ml). The serum total protein in these dogs fell in the early postoperative period due to the fall in serum albumin which reached its lowest value (mean 29 g/l, range 22–36 g/l) on the third day after the operation (*Fig.* 5), thereafter gradually returning to a mean value slightly in excess of the preoperative value.

The BSP test showed a variable pattern in dogs after partial hepatectomy preceded by inflow occlusion. All 15 dogs had an early increase in retention (mean 24 per cent, range 11–43 per cent on the second postoperative day). In 5 dogs after 30 minutes of ischaemia the changes were essentially similar to those in group II animals. However, in the other 10 dogs after ischaemia for 45 or 60 minutes 7 animals showed a late rise to between 12 and 42 per cent retention at various times between the third and sixth weeks. In 4 of these dogs the tendency was a return towards normal values after this late rise, but in 2 animals a progressive elevation was recorded and in another dog a third increase occurred in the fifth and sixth weeks. The changes in the animals after 60 minutes' ischaemia are illustrated in *Fig.* 6.

Restoration of liver mass in these dogs showed a mean of 83 per cent (range 76–100 per cent) of the estimated preoperative weight.

Discussion

The main purpose of the investigation was to examine the changes in liver function which occur in partially hepatectomized animals in whom the liver remnant has suffered a period of ischaemia prior to hepatectomy. In severe hypovolaemic shock in human subjects, hypoperfusion of the liver may contribute to liver damage resulting in impairment of liver function after partial hepatectomy; recently, doubt has been cast on the release of endotoxin into the portal circulation as an important mechanism in prolonged hypovolaemic shock in man (Herman et al., 1974), and although other toxic substances may exist in blood from a hypoperfused gut, the effect of ischaemia itself on the liver requires further definition.

Perhaps the most important conclusion from these experiments is that ischaemia of the liver remnant for up to 1 hour is compatible with survival in the dog. None of the major problems encountered in clinical practice, including severe hypoglycaemia and coagulation defects, was seen in these animals. No comparable series of ischaemia to the liver remnant has been reported, but the overall survival rate of 88 per cent with 83 per cent surviving 60 minutes of inflow block and subsequent 70 per cent hepatectomy is better than that of 50–60 per cent survival reported after 60 minutes' inflow block to the whole liver with portal diversion (Farkouh et al., 1971).

There is no doubt that ischaemia was complete in these experiments since this was confirmed by the ^{133}Xe clearance method. It is possible that portal decompression by diversion through the lobes subsequently resected and also the increased rate of flow through the remnant after hepatectomy contributed considerably to this high survival rate.

Examination of measurements made in control animals shows that only minor changes in the biochemical tests of liver function occur after laparotomy alone. The more severe changes in liver function tests found after 70 per cent hepatectomy alone establish a pattern of biochemical changes including an increase in serum alkaline phosphatase and transaminase together with a fall in serum albumin; these changes show a return towards normal values during the period of survival. Similarly, an abnormal increase in BSP retention occurs only in the early postoperative period. These findings substantiate those of previous studies (Aronsen and Ericsson, 1968; Flatmark et al., 1973) with only small differences. One of the surprising features in this and other studies is the small increase in serum bilirubin which returns to preoperative levels within the first week after hepatectomy. We have not found a peak value occurring later in the postoperative period (3 weeks), as described by Flatmark et al. (1973) in dogs undergoing hepatectomy alone.

As an index of the synthetic function of the liver, the fall in serum albumin takes some weeks to recover and indicates impairment of this aspect of liver function. The changes recorded are similar to those reported by Aronsen and Ericsson (1968) after 35–60 per cent partial hepatectomy.

Animals in which the liver remnant was rendered ischaemic were treated as a single group for analysis of liver function tests although the period of ischaemia ranged from 30 to 60 minutes; a relatively small number of animals justifies this method. In comparing the effects in this group with those which follow hepatectomy alone, the most striking differences are in the alkaline phosphatase and SGPT. The progressive increase in alkaline phosphatase is in sharp contrast to the steady return towards normal values which characterizes a straightforward partial hepatectomy. The reasons for this are obscure since in these animals the absence of a sustained rise in bilirubin excludes major excretory obstruction as a cause. Also opposing obstruction as an explanation for the escalating alkaline phosphatase is the normal BSP retention in some animals in the later postoperative period. There is certainly no clear correlation between a late rise in alkaline phosphatase and abnormal BSP retention, although these two features were concurrent in the majority of animals.

In the present study proliferation of hepatoctyes after hepatectomy (i.e. 'regeneration') was not studied; the major changes in mitosis and in DNA synthesis are known to occur soon after hepatectomy and are over by the sixth postoperative week. However, the end result of regeneration, regrowth of the liver towards its preoperative weight referred to here as 'restoration of liver mass', was measured in each hepatectomized animal. The remarkable capacity for regrowth was evident in both experimental groups, but a comparison of liver weights shows that the restoration of liver mass was slightly less at 6 weeks (83 per cent) after ischaemia than after hepatectomy alone (91 per cent). Although this difference is statistically significant, there is considerable overlap in the individual measurements which comprise these groups. It is therefore reasonable to conclude that in terms of liver weight no important effect is found 6 weeks after ischaemia of up to 60 minutes' duration.

In conclusion, these results cast doubt on the belief that the liver is extremely sensitive to short periods of ischaemia, although in this case the observations have been made on the dog liver, in contrast to the majority of observations made on the pig liver. Studies related to transplantation have suggested that 'warm ischaemia time' (which is analogous to the period of normothermic ischaemia in our animals) must be less than 30 minutes to ensure survival (Peacock et al., 1969), although it may be said that the procedure of transplantation, together with any immune reaction, is an additional stress for the organ in that situation. Battersby et al. (1974) have recently confirmed that the pig liver can withstand total normothermic ischaemia of 30 minutes if portal diversion is incorporated, and interestingly have shown by transhepatic sampling in the acute phase of ischaemia the initiation of elevated alkaline phosphatase and transaminase which we have demonstrated in the later period of survival.

In relation to liver resection which was the prime purpose of this study it is interesting to find that the restoration of liver mass is not severely impaired by a period of complete ischaemia. Initial results from a study of more prolonged ischaemia (currently in progress) show that hypoglycaemia and major coagulation abnormalities do occur in the dog in these circumstances and are accompanied by a significantly higher mortality. There may therefore be a very narrow margin between preservation of function, including the ability of the liver to regenerate, and failure of function resulting in death of the animal. From these experiments it appears that the critical period of total ischaemia in the dog is not less than 60 minutes.

Orthotopic liver transplantation utilizing a vascular stapling instrument

P. T. BARRON, I. J. VOGELFANGER AND W. G. WADDELL*

SUMMARY

A technique of orthotopic liver transplantation in the pig is described in which the main feature is the accomplishment of four of the five anastomoses by the use of the Vogelfanger NRC vascular suturing instrument. The advantage of this instrument is the rapid accomplishment of safe leak-proof anastomoses.

DESCRIPTIONS of orthotopic liver transplantation in the pig have been reported by many authors (Garnier et al., 1965; Cordier et al., 1966; Mieny et al., 1967; Terblanche et al., 1967; Calne et al., 1968; Chalstrey et al., 1971). The surgical technique is of critical importance. The incidence of complications is frequent and often fatal. The most dangerous period is that interval during implantation of the donor liver when the recipient animal is totally bereft of liver function. It is vital, therefore, to restore hepatic blood supply promptly, and if this anhepatic period is prolonged beyond 45 minutes serious and often irreversible metabolic acidosis occurs. The usefulness and versatility of the Canadian Vogelfanger NRC vascular stapler (Vogelfanger et al., 1962, 1967) suggested an application to liver transplantation where rapidity in the performance of the vascular anastomoses is so desirable. The use of this instrument and modifications in the operative technique are described.

Materials and methods

Pigs of differing breeds, White Landrace and Black Poland China, of approximately 30 kg were used.

Donor

Through a subcostal incision the donor liver was freed from all its ligamentous attachments, and the portal vein, hepatic artery and common bile duct were dissected to the superior border of the pancreas.

The subhepatic vena cava was isolated down to the renal vein, avoiding injury to the suprarenal vessels. The triangular ligaments above the liver were divided and phrenic veins draining into the suprahepatic inferior vena cava ligated. The liver was cooled *in situ* through the portal vein with Ringer's lactate solution containing 10 ml of 8·4 per cent sodium bicarbonate, 200 mg of lidocaine, 1 ml of heparin and 100 mg of hydrocortisone per litre. Hepatectomy was then performed, preserving as much of the donor vessels as possible.

Recipient

The following parameters were monitored: arterial pressure, central venous pressure, temperature, ECG and serial estimations of $P\text{CO}_2$ and standard bicarbonate. Hepatectomy was performed in the same manner as in the donor. On a number of occasions it was necessary to ligate the gastroduodenal artery but no damage to the duodenum was observed. Portosystemic shunt was performed by cannulation from the splenic to the jugular vein following splenectomy. Heparinization was performed with 0·5 mg of heparin per kg. The donor liver was implanted into the recipient and the anastomoses done in the following order: suprahepatic vena cava, portal vein, hepatic artery, infrahepatic vena cava and common bile duct. The suprahepatic inferior vena cava anastomosis was done as a single layer continuous suture utilizing 3/0 silk. End-to-end anastomoses between the donor and recipient portal vein, hepatic artery, subhepatic inferior vena cava and common bile duct were performed with the Vogelfanger NRC vascular stapling instruments (Vogelfanger et al., 1962, 1967), Mark IV (handling vessels 2–5 mm in diameter) and Mark XII (for vessels 6–12 mm in diameter).

The key components of the vascular staples are the stapling bushing with the U-shaped tantalum staples and a corresponding anvil bushing with appropriately shaped moulding surfaces to bend the staples (*Fig.* 1).

The vessel diameters were first measured. Vessel size ranged from 10 to 12 mm for the portal vein and subhepatic inferior vena cava, and from 2 to 3 mm for the hepatic artery. The diameter of the common bile duct was approximately 5–6 mm.

Cuffs of donor and recipient vessels were then everted over the driving and anvil bushings respectively and held in position by plastic rings (*Figs.* 2, 3). In the larger vessels this was done by hand, and in the hepatic artery was readily achieved by an everting instrument. The two handles were locked together and the staple-driving mechanism operated to drive the staples through the vessel wall, towards the anvil bushing, moulding the driven staples in the shape of a letter B, thus forming an interrupted mattress suture. Removal of the instrument left a stapled vascular anastomosis.

When the portal anastomosis was completed the vascular clamp was removed and the liver perfused with 300–400 ml of portal venous blood which was allowed to egress into the abdominal cavity through the infrahepatic vena cava. In the preceding few

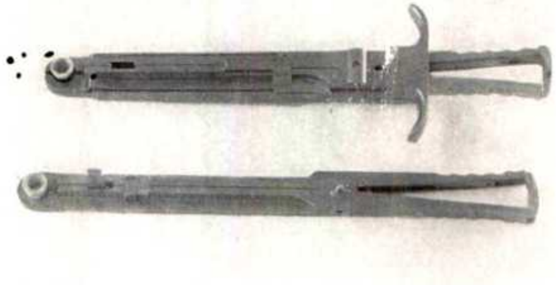

Fig. 1. Instrument disassembled.

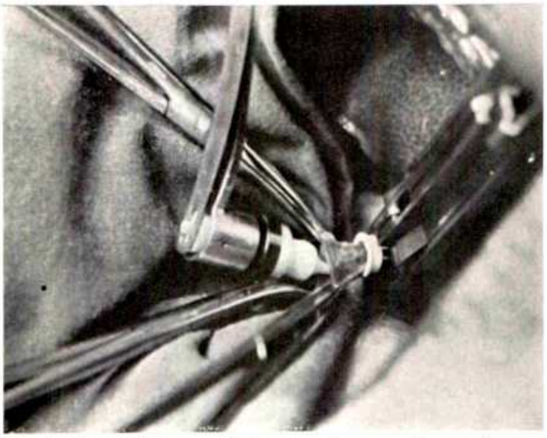

Fig. 2. Evertor being applied to produce a cuff over the bushing of the closed instrument.

minutes the animal had been transfused with a unit of blood to allow for this loss. The subhepatic inferior vena cava was then clamped and the vascular clamps on the suprahepatic inferior vena cava were removed to restore portal to systemic circulation. The remaining anastomoses including the common duct were then completed rapidly, utilizing the same technique (*Fig*. 4).

The time taken to complete the three critical anastomoses—suprahepatic vena cava, portal vein and hepatic artery—was approximately 15–20 minutes using this technique.

Prior to closure of the abdomen and neck, vagotomy and pyloromyotomy were done (Calne et al., 1968).

Discussion

The complexities of liver transplantation relate to technical problems, the susceptibility of the liver to ischaemia and the tendency of the animal to develop serious metabolic problems during the anhepatic period. For this reason the ischaemic interval for the graft and the anhepatic period in the recipient should be as short as possible. A functioning portosystemic circulation is achieved quickly by first completing the suprahepatic vena cava anastomosis and then the portal vein, and immediately allowing a flow through the liver. The use of the Vogelfanger NRC vascular stapling instrument allows the rapid completion of these anastomoses, and in our hands shortens the anhepatic time to under 15 minutes. The hepatic artery and infrahepatic vena cava anastomoses may then be equally rapidly completed, allowing the total time for the vascular anastomoses to be under 45 minutes.

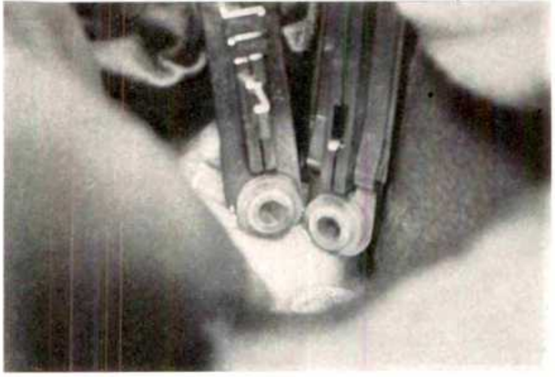

Fig. 3. Both cuffs everted with nylon rings left by the evertor for fixation of the cuffs. Handles ready for assembly.

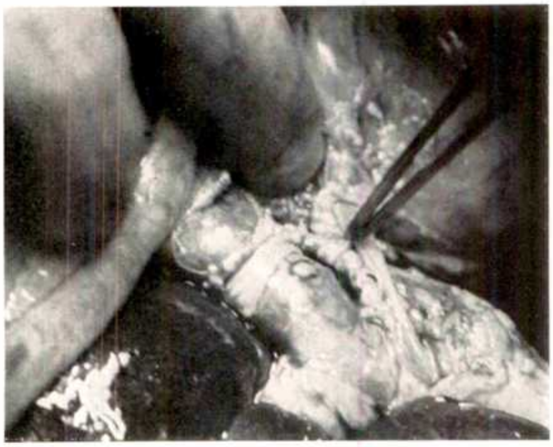

Fig. 4. Completed anastomosis of the portal vein (left), hepatic artery (right) and common duct (above the hepatic artery).

The instrument gives a very precise intima to intima leak-proof anastomosis with a high degree of long term patency (Vogelfanger et al., 1962, 1967). A small vessel anastomosis with this technique also minimizes the trauma to the liver consequent upon dissection of the hepatic artery down to the coeliac artery and aorta which is necessary when a larger vascular reconstruction is done.

A series of 31 liver transplants was done utilizing this method, with an operative mortality of 7 and with 12 animals surviving for 6–160 days.

Effect of surgical trauma on plasma concentrations of cyclic AMP and cortisol

G. V. GILL, K. PRUDHOE, D. B. COOK AND A. L. LATNER*

SUMMARY

The response of plasma cortisol and cyclic AMP concentrations to surgical trauma was examined in 7 general surgical patients. Five patients made uncomplicated recoveries and showed peak cortisol levels at 6 hours postoperatively, returning to normal by 24 hours. One patient developed postoperative pneumonia and the plasma cortisol remained elevated up to 48 hours, and the final patient showed no cortisol response at all. The plasma cyclic AMP concentrations showed a consistent rise during the operation itself, which was statistically significant when compared with preoperative levels ($P<0{\cdot}0125$). Concentrations had fallen to normal by 6 hours in all the cases, except in the patient who developed pneumonia, where the plasma cyclic AMP also showed a prolonged elevation. The significance of these findings requires further elucidation, but the temporal relationship of the cyclic AMP and cortisol peaks would support the hypothesis that cyclic AMP may play a part in the mediation of ACTH release following surgical trauma.

THE intracellular role of cyclic AMP (adenosine 3′,5′-monophosphate) as a mediator of hormone action is well established (Robison et al., 1971). Recently, however, improved assay techniques have enabled cyclic AMP to be demonstrated in human plasma (Kaminsky et al., 1970). The function, if any, of this free extracellular nucleotide is at present uncertain, but preliminary work suggests that its concentration is at least to some extent hormone-dependent. Thus the intravenous infusion of high doses of glucagon (Broadus et al., 1970) and parathormone (Kaminsky et al., 1970) into healthy human subjects is associated with raised plasma cyclic AMP concentrations.

In order to examine the role of cyclic AMP in more physiological hormonal responses we have studied plasma cyclic AMP levels in relation to the cortisol response to surgical operation. Our results indicate significant elevations in plasma cyclic AMP concentrations during surgery, and this increase precedes the peak postoperative plasma cortisol elevation.

Patients and methods

Subjects were drawn from general surgical units. Patients with known endocrine diseases or undergoing only minor surgery were excluded; otherwise selection was completely random. Seven patients were studied. Blood samples were taken preoperatively (usually the morning of surgery), peroperatively (half-way through the operation), 6 hours postoperatively (timing from the beginning of surgery) and 24 hours and finally 48 hours after operation. Blood was taken from an antecubital vein with minimal venestasis, collected in heparinized tubes, immediately centrifuged at 4 °C, the plasma separated and then deep frozen at −20 °C. Plasma cortisol was measured by the competitive protein-binding method of Murphy (1967), adapted for ultramicro use by using dog plasma as the source of corticosteroid-binding globulin. Plasma cyclic AMP was also measured by a protein-binding technique (Latner and Prudhoe, 1973) developed from the method of Brown et al. (1971). The normal range for the plasma assay was 12–20 nmol/l.

Results

There were three types of cortisol response observed in the 7 patients.

1. '*Normal responders*'

Five patients underwent successful surgery and made an uncomplicated postoperative recovery. These subjects showed what may be called a 'normal' cortisol response, with levels peaking at 6 hours postoperatively and being almost back to normal by 24 hours (Johnston, 1972). The plasma cyclic AMP response in each of these patients was at its peak in the peroperative sample and had almost returned to normal by 6 hours after surgery. These results are shown in *Fig*. 1, and it will be seen that the responses are statistically significant.

2. '*Prolonged responders*'

It is known that high cortisol levels may persist after surgery if complications ensue (Birke et al., 1957). One patient in our series developed postoperative pneumonia, and the prolonged cortisol response is shown in *Fig*. 2. The plasma cyclic AMP level also remained elevated.

3. '*Non-responders*'

It has been known for some time that about 20 per cent of surgical patients show little or no cortisol response to operation (Thomasson, 1959; Espiner, 1966). In the present series 1 patient (who in fact underwent a combined rectal excision) showed this phenomenon, although a peroperative plasma cyclic AMP rise was again demonstrated (*Fig*. 3).

Discussion

The elevation of plasma cortisol concentration following surgical trauma is mediated by corticotrophin (ACTH), as shown by Ichikawa et al. (1971). The work of Hume et al. (1962) suggested that afferent nervous impulses from traumatized tissue to the

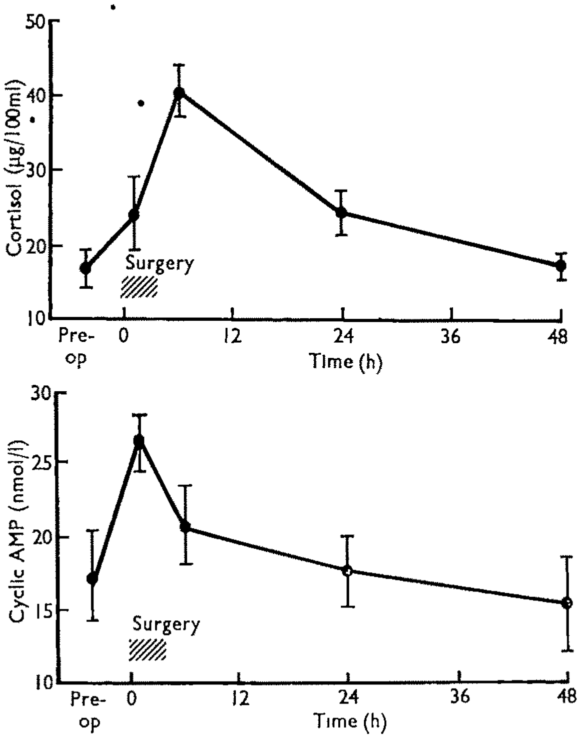

Fig. 1. Mean cortisol and cyclic AMP response (±standard error) to surgery in 5 patients. The differences between the preoperative and 6-hour levels of cortisol and between the pre- and peroperative levels of cyclic AMP are significant (0·0125>P>0·010).

hypothalamus stimulated ACTH release, but more recently it has been shown that animals with denervated pituitary glands can show a cortisol response to stress (Greer, 1970; Witorsch and Brodish, 1972), suggesting that a humoral factor or factors must exist. Cyclic AMP has been shown *in vivo* to elevate plasma cortisol levels, both in piglets (Cook et al., 1974) and in man (Angeli et al., 1973). The work in piglets has shown that the primary action of cyclic AMP is to stimulate ACTH release from the pituitary, and also that this action is shared by adenosine and other adenine nucleotides (Cook et al., 1974, 1975). As long ago as 1950 Green and Stoner provided evidence that release of adenine compounds into the circulation could mediate the cardiovascular response to trauma. They also provided some evidence that these compounds may be involved in the adrenocortical response to trauma (Stoner and Green, 1950).

Our results are consistent with the hypothesis that cyclic AMP (and possibly other compounds of adenine) exert a humoral action in the homeostatic responses to surgical trauma. The plasma cyclic AMP levels were at a peak before those of cortisol in each case. In the 1 patient who developed complications the plasma cyclic AMP remained elevated, as did the plasma concentration. The 'non-responder' showed a normal cyclic AMP peak during surgery, and thus may have an 'end organ failure' of cyclic AMP stimulation.

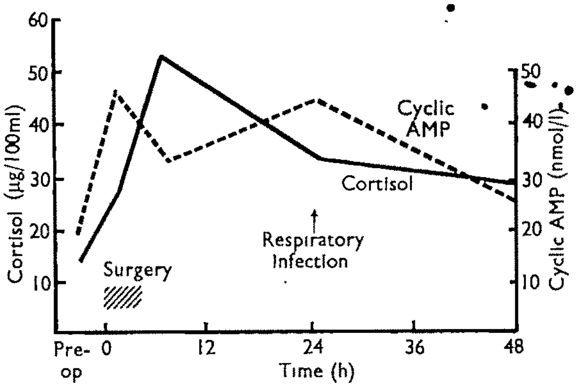

Fig. 2. Prolonged cortisol and cyclic AMP response to surgery in a patient developing a postoperative respiratory infection.

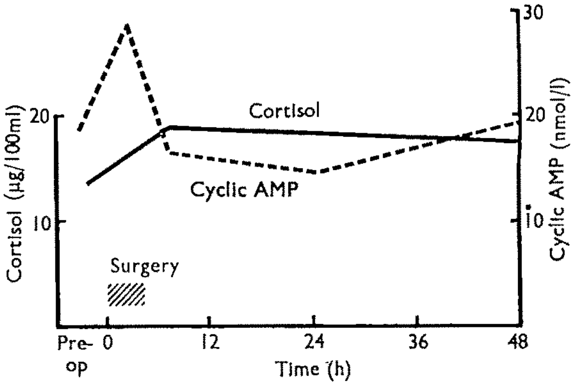

Fig. 3. Absence of cortisol response with a normal rise in cyclic AMP in a patient undergoing a combined rectal excision.

An intriguing problem is the source of the elevated plasma cyclic AMP levels which we have described. These may be merely a reflection of increased corticotrophic or other hormonal activity during and following surgery. It is possible that cyclic AMP and other nucleotides could be released directly from traumatized tissue during operation. However, although our series is small we did not notice any correlation between the degree of trauma and the magnitude of the cyclic AMP peak (Ichikawa et al. in 1971 also failed to correlate the degree of trauma with plasma ACTH peaks). Also, the nucleotides released from damaged tissue would be diluted in the extracellular fluid and subjected to rapid degradation, making it unlikely that any effect on peripheral plasma levels would be observed. A more likely explanation is that cyclic AMP and possibly other adenine compounds escape into the extracellular fluid from all cells as a result of the increased cell membrane permeability which is known to occur during surgery (Flear, 1972). Adenine nucleotides and nucleosides have been previously shown to be capable of crossing cell membranes intact (Axelsson and Holmberg, 1969; Chaudry and Gould, 1970).

However, although we may have demonstrated a true cause and effect relationship between cortisol and cyclic AMP, so many other hormone systems are involved in the response to trauma that one can only hypothesize on our results. Thus, the isolated rat liver will secrete cyclic AMP when perfused with catecholamines (Exton et al., 1972), and this may be of some physiological significance in man. Vetter et al. (1974) have found a significant correlation between plasma levels of cyclic AMP, insulin and glucose during the hours following myocardial infarction. Finally, we do not know the effect of anaesthesia *per se* on plasma cyclic AMP concentrations. Further work is required to elucidate these complex problems.

Early management of corrosive burns of the oesophagus

M. BALASEGARAM*

SUMMARY

One hundred and sixteen patients with early corrosive burns of the oesophagus treated by the author are reviewed. It is emphasized that the all important aspect of management of these patients is prophylactic treatment to avoid stricture of the oesophagus. Early treatment consists of intravenous fluid therapy, broad spectrum antibiotics, sedation, parenteral hydrocortisone and more importantly maintaining the patency of the oesophagus followed by dilatation. The importance of early barium meal studies and oesophagoscopy is stressed.

INGESTION of corrosive liquids is still one of the commonest forms of suicide in Malaysia, especially amongst the lower social class. While a number of instances result in immediate death, most survive to suffer the disabling sequelae of stricture formation of the pharynx, oesophagus or even the stomach. The management of these patients has become a challenging problem.

This article expounds a personal experience in the management of 116 patients with early corrosive burns treated at the General Hospitals of Seremban and Kuala Lumpur, Malaysia, from January 1964 to July 1974. The basis of treatment is the prevention of the development of strictures of the oesophagus following ingestion of the corrosive liquids during the acute phase, thereby reducing the need for surgical replacement.

Materials and methods

The commonest corrosive agent used for attempted suicides was concentrated sodium hydroxide or lye. Other agents included acetic or formic acid and various alkali-containing detergents. Prior to 1964 all patients with early oesophageal burns were admitted and initially treated by the physicians in the medical units. The patients who later developed strictures or stenosis were then referred to the author for further surgical management. Since 1964 almost all the patients with early corrosive burns were admitted directly under the author's care. There were 116 patients in all. Eighty of these patients were females. More than 85 per cent were between the ages of 18 and 30 years. Seventy (60·3 per cent) were of Indian origin, while the rest were Chinese. No Malaysian case was recorded. Marital problems and family disputes including failure to achieve their desired objectives were the commonest reasons for attempting suicide.

Treatment

Early treatment of these patients was aimed at the prevention of strictures or stenosis of the corrosive burns of the pharynx or oesophagus. It consisted of intravenous fluid therapy, broad spectrum antibiotics, sedation and parenteral hydrocortisone in doses of 200 mg every 6 hours. The most important aspect, however, was to maintain the patency of the oesophagus, keeping the lumen of the oesophagus open by means of a Ryle's or Levin's tube passed immediately after admission. Early barium studies and oesophagoscopy were performed to assess the depth and extent of the burns, and appeared to provide an adequate assessment of the extent of injury. Early oesophagoscopy has been shown to be safe, provided that a small instrument is introduced with care and not taken beyond the area of the burns. This regimen was maintained for a period of 3 weeks. The barium studies were repeated on the first and third weeks and subsequently after 3 months or when necessary. All the burns in this series were either deep or intermediate involving the muscularis or the entire depth of the walls of the oesophagus (*Fig.* 1).

After 3 weeks, dilatation therapy was commenced under general anaesthesia in all the patients. More recently, in the light of earlier experience, dilatation has been performed after 10 days. The patients were dilated weekly for 6 weeks, and later monthly for 6 months to a year. They were all seen regularly for up to 3 years, and were advised to see the author immediately if any difficulty in swallowing solids was noted. Sixty-four patients required dilatation for 6 months while the remainder necessitated a year's dilatation.

Results

Ten of the 116 patients were admitted in a state of shock, and these all died within a few days of admission in spite of vigorous resuscitation. Autopsy revealed extensive necrosis of the oesophagus and stomach with perforation and mediastinitis.

Of the remaining 106 patients, 8 patients developed strictures of the oesophagus and 3 of the pharynx and larynx. Most of these patients were mentally ill and refused to cooperate with the present treatment regimen. Replacement surgery of the oesophagus and pharynx was performed in these 11 patients using pedicled grafts involving reversed gastric tubes, jejunum or colon.† Three patients developed pyloric stenosis requiring gastro-enterostomy. Three of the 4 patients treated by bouginage developed perforation of the oesophagus. In the fourth the stomach was the site of perforation (*Fig.* 2*a*). Perforation of the oesophagus was treated by intercostal drainage, intravenous fluid

† Forty-five other patients also had replacement therapy during this period but they were either not treated initially during this period or were referred to the author from other centres. All had established strictures of the pharynx or oesophagus.

therapy and antibiotics for 3 weeks. These patients recovered fully and were subsequently treated by dilatation. The patient with the perforated stomach refused surgery and died from peritonitis.

Discussion

Corrosive burns of the oesophagus constitute a significant problem in Malaysia because of the common development of severe strictures. Little interest has previously been taken in this persistent problem.

The injury that results from ingestion of corrosive liquids has been well documented (Haller and Bachman, 1964). It is well known that burns in the oral cavity do not necessarily imply extension of the pathology into the oesophagus. Neither is absence of oral burns an indication that there are oesophageal or gastric burns. Clearly the early use of barium studies and oesophagoscopy is of prime importance in first establishing the diagnosis (Knox et al., 1967; Haller, 1971).

It is our view that the classification of oesophageal burns into 'superficial', intermediate' and 'deep' depending on the degree of penetration of the caustic liquid is important. This classification reflects the late changes associated with the healing process which results in subsequent stricture formation. The degree and extent of these changes are proportionate to the length and depth of the acute burns, which in turn are directly related to the amount and concentration of the corrosive liquid consumed and to the duration of its retention in the oesophagus (Storey, 1962). Autopsy reports of patients who died of very extensive burns showed complete destruction and sloughing of the entire lining of the mucosa and muscularis with mediastinitis, and even perforation of the oesophagus and stomach. Many of these patients die within 12–48 hours. In those who survive the damage involved all the layers of the oesophagus, the result being a dense hard fibrotic oesophagus (Cleveland et al., 1963).

Patients with intermediate burns often survive and manifest gangrene of the mucosa due to thrombosis of the submucosal walls with sloughing of the mucosa and submucosa. The sloughing is replaced by granulation tissue which in time is again replaced by fibrous tissue (Burford et al., 1953). In short, the depth of the fibrosis depends upon the severity of the original burn. In all our patients the burns were either deep or intermediate, no doubt because they had swallowed the caustic liquid in large volumes and high concentration with real suicidal intent.

Superficial burns involve only the mucosa, and re-epithelization can be anticipated with little or no evidence of fibrosis or stricture formation. This was confirmed by oesophagoscopy and barium meal studies. In deep burns the appearance of the oesophagus is one of post-inflammatory fibrosis with long strictures and often involvement of the entire circumference of the oesophagus.

The Salzer method of treating corrosive burns introduced in 1920 which consisted of early bouginage was considered unsatisfactory because there was no antibiotic cover at that time to prevent pulmonary or mediastinal infection.

Later, early steroid therapy which was known to prevent inflammatory response was adopted since the major inflammatory reaction occurred during the first 24–48 hours (Viscomi et al., 1961; Webb et al., 1970). This is in keeping with the findings of Palmer (1952), who noted that 80 per cent of all strictures occurred in the first 8 weeks after the burns. However, while the principle of immediate steroid–antibiotic therapy and bouginage appears to be sound, the incidence of oesophageal strictures was still very high indeed. With the advancement of oesophageal surgery, surgeons enthusiastically regarded oesophageal replacement of the oesophagus by stomach, jejunum or large intestine as the best form of treatment (Balasegaram, 1968).

The goal of our present treatment is to forestall late stricture formation by maintaining the patency of the oesophagus and the pharynx by immediate insertion of a Ryle's or Levin's tube on admission, thus keeping the lumen of the pharynx and oesophagus patent, together with commencement of early dilatation. The aim is to salvage an active peristaltic oesophagus into a non-peristaltic pipe-stem tube or a conduit with a lumen of sufficient diameter to enable the patient to swallow, avoiding the hazards of oesophageal surgery. We also believe that these patients are better managed by a surgeon who is particularly interested in this problem, especially as instrumentation and management of complications can be dealt with by him.

However, it must be admitted that in spite of all these measures, replacement surgery was sometimes necessary because of: (*a*) the presence of multiple strictures; (*b*) frequent dilatation; (*c*) failure or refusal of the patient to turn up for regular dilatation; (*d*) high strictures or a fistula between the oesophagus and the trachea or bronchus (*Fig*. 3*a*); (*e*) socio-economic and, more important, psychological reasons. The psychological treatment of these patients is one of the all important factors, considering their state of mind. The very fact that only 12·7 per cent of the patients required replacement surgery with the current form of treatment supports the author's argument.

It is important to note that in this series Indians formed 60·3 per cent of the patients although they comprise only 11 per cent of the population of Malaysia. This is clearly due to the easy availability of corrosive substances in rubber estates where most of them are employed. The Chinese who form 38 per cent of the population had an incidence of only 39·7 per cent. They prefer various forms of drugs or jumping from high buildings and self-immolation. It is the author's opinion that while barbiturates are a kinder form of suicide and popular among the upper class, such attempts are more easily treatable and do not result in agonizing death by comparison with corrosive liquids. Unfortunately, attempted suicide by corrosive liquids does not necessarily end in death and the subsequent suffering of the patient is quite tragic (Balasegaram, 1972).

In conclusion it must be stressed that the all important aspect of management of early corrosive burns is prophylactic treatment to avoid strictures of the oesophagus. A big step forward has therefore been taken and new findings and developments can be expected from the author's present management. However, the real answer to this problem and one that is currently under discussion is Government legislation on the sale and control of corrosive liquids.

Addendum

Since this paper was prepared the author has successfully treated by the present regimen a further 7 cases of suicidal corrosive poisoning due to ingestion of lye.

The management of peptic oesophageal stricture

R. C. N. WILLIAMSON*

SUMMARY

Eighty-three adult patients with peptic oesophageal stricture are reviewed with regard to diagnosis and treatment. Sliding hiatus hernia was present in 94 per cent of cases. The strictures were graded according to the degree of stenosis encountered at initial oesophagoscopy, but several other factors influenced the management of each case. Bouginage should always be attempted before proceeding to surgery. Thirty-eight patients were treated by bouginage alone, with 21 (55 per cent) good results and 3 deaths. Forty-five patients came to surgery, with 32 (71 per cent) good results and 3 deaths. Six patients sustained instrumental perforation of the oesophagus with 1 fatality. There was in addition 1 case of silent perforation following self-bouginage, which is believed to be unique. Hiatal herniorrhaphy combined with simple bouginage is recommended where reflux oesophagitis dominates the clinical picture. Local plastic repair (oesophagoplasty) has proved a simple and effective method of treating low annular strictures. Oesophagogastrostomy was carried out in 12 patients without operative loss and with good results in 8 cases; the addition of a pyloroplasty is believed to lessen postoperative reflux.

INJURY to the oesophagus may cause submucosal scarring, leading to permanent stenosis. In this country the commonest injurious agent is gastro-oesophageal reflux, but treatment of the resultant peptic stricture remains controversial. It has been stated that 'bouginage should be the method of choice in every case unless one is dealing with severe haemorrhage or perforation' (Benedict, 1966). Most British surgeons, however, advocate operation for the majority of cases (Editorial, 1968), though this may vary from local plastic repair to extensive resection with oesophageal replacement. The present communication reviews a large series of patients with peptic oesophageal stricture, with particular regard to their diagnosis and treatment in a district thoracic surgical unit.

Patients

The series comprises 83 patients with peptic stricture treated at Peppard Hospital, Oxfordshire, during the 10-year period 1962–71 under the care of one consultant thoracic surgeon. *Table I* shows that this was by far the commonest aetiological type of benign oesophageal stricture seen during this period. All the patients were followed up for a minimum of 2 years after treatment. The total includes 49 women and 34 men, aged from 14 to 89 years with a mean of 68·2 years. The maximal incidence occurred during the seventh and eighth decades, two-thirds of patients being over the age of 70. Not surprisingly this elderly population had a high incidence of cardiorespiratory disease, 11 patients being severely incapacitated.

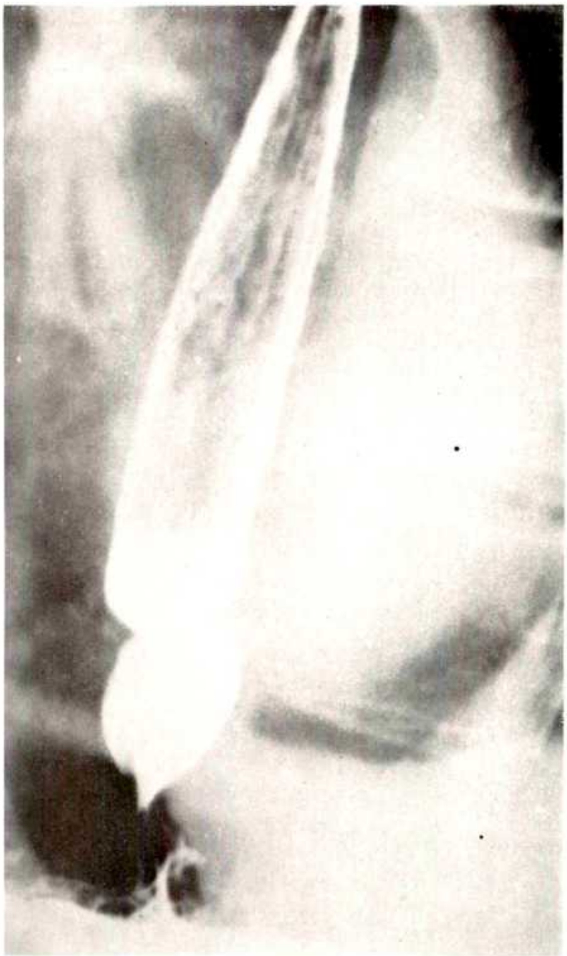

Fig. 1. Barium swallow film showing an early annular stricture of the lower oesophagus. This caused surprisingly severe symptoms but was successfully treated by local plastic repair (oesophagoplasty).

Fig. 2. *a*, 'Ascending oesophageal fibrosis'. Barium swallow film showing an elongated peptic stricture. *b*, The appearance on a barium swallow film following resection of the stricture with jejunal replacement. The patient obtained an excellent result.

Sliding hiatus hernia was demonstrated in 78 of the 83 cases (94 per cent), while the remaining 5 patients all had clinical and endoscopic features of reflux oesophagitis. Three patients with no antecedent gastro-oesophageal symptoms developed an acute postoperative stricture, in each case following colonic surgery.

Diagnosis

Clinical

Table II shows that dysphagia was the only constant symptom. It varied greatly in severity and duration and 7 patients presented with complete oesophageal obstruction (aphagia). It is notable that one-third of the patients had no previous history of reflux oesophagitis.

Radiological

Apart from 2 patients with aphagia who underwent emergency oesophagoscopy, all the strictures were first demonstrated by barium swallow examination. *Figs.* 1 and 2 illustrate the two classic types, namely annular stricture caused by a localized ring of fibrous tissue, and ascending oesophageal fibrosis (Kelly, 1936) where scarring extends for several centimetres with muscular hypertrophy, peri-oesophagitis and mediastinal adenopathy. In 12 strictures subsequently shown to be benign there was radiological suspicion of carcinoma; 5 of these also appeared irregular at endoscopy so that the possibility of carcinoma became a major factor in advising surgery. *Fig.* 3 demonstrates another pitfall in radiological diagnosis.

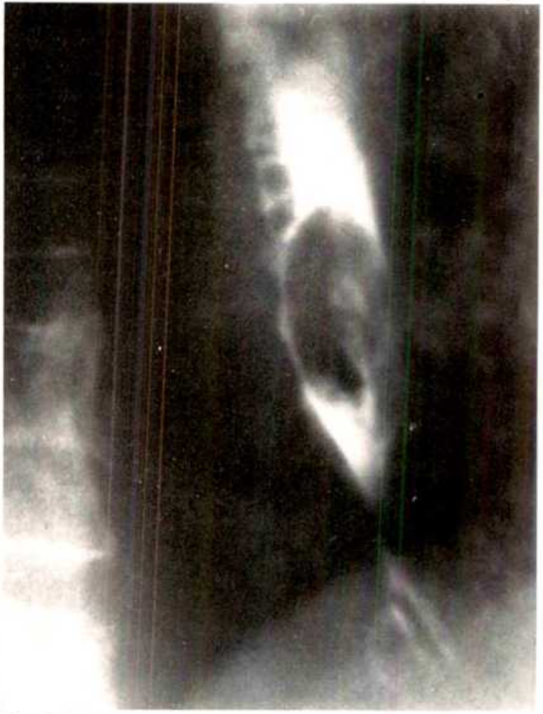

Fig. 3. Barium swallow film magnified to show a rounded filling defect in the lower oesophagus. This was reported as a leiomyoma but at thoracotomy the 'tumour' proved to be a peanut, swollen and impacted above an annular stricture. Oesophagoplasty was successfully performed.

Table II: SYMPTOMS OF PEPTIC STRICTURE

Symptom	No. of cases	%
Dysphagia	83	100
Reflux oesophagitis (heartburn, acid brash etc.)	55	66
Regurgitation of solids	42	51
Weight loss (>6·3 kg)	19	23
Haematemesis	8	9
Inhalation pneumonitis	5	6
Hiccup	5	6

Endoscopic

In nearly every case the presence of a stricture was confirmed at oesophagoscopy and definitive treatment by bouginage was attempted at the same time. Some degree of oesophagitis was observed in 45 patients (54 per cent). *Fig.* 4 shows that the large majority of peptic strictures were confined to the lower third of the oesophagus, as expected. The strictures were graded according to the degree of stenosis encountered at the initial oesophagoscopy as follows:

Grade I: Slight stenosis easily negotiated.
Grade II: Moderate stricture dilated without difficulty.
Grade III: Tight stricture only dilated with difficulty.
Grade IV: Impassable stricture.

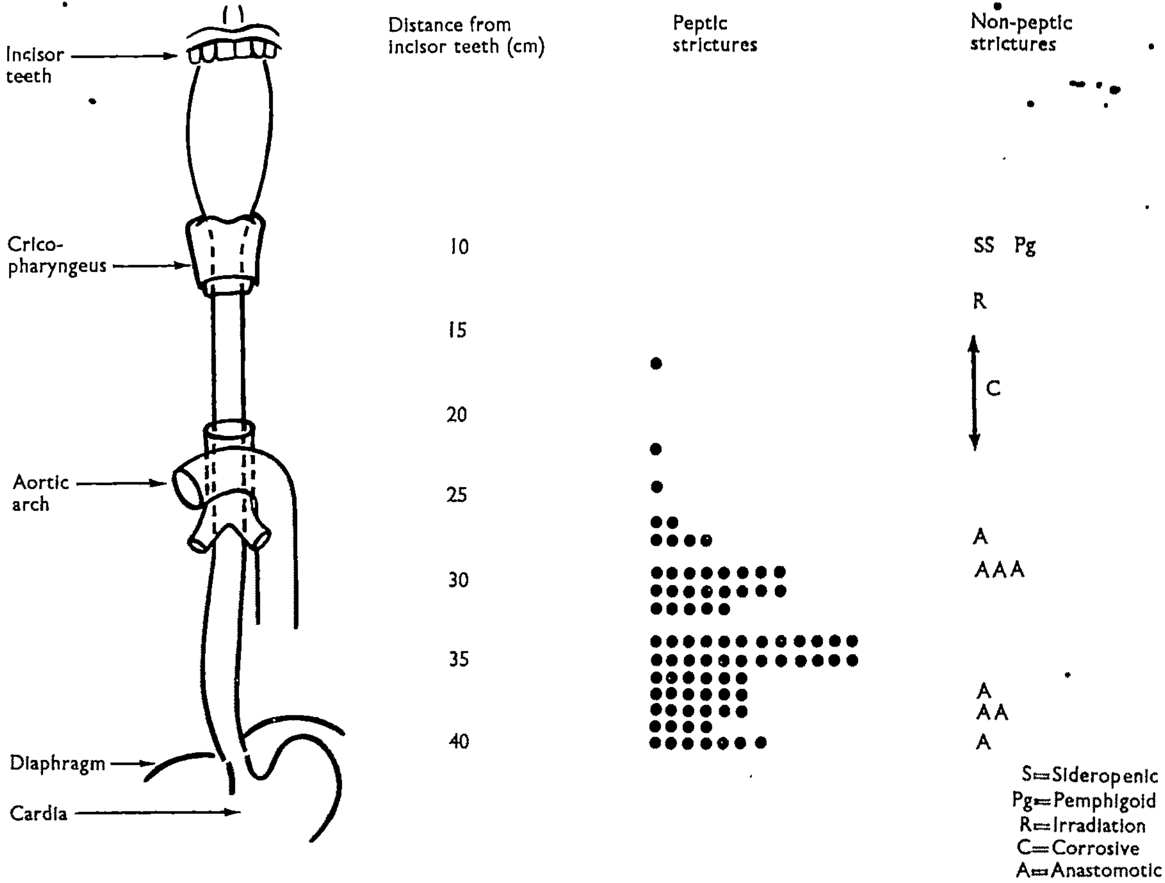

Fig. 4. Diagram to show the level of benign oesophageal strictures at endoscopy. Each peptic stricture is marked by a black circle. Strictures of non-peptic origin are included for comparison. The highest peptic stricture was found at 18 cm from the incisor teeth; it proved amenable to bouginage.

Histological

In 53 patients carcinoma was excluded as far as possible by the examination of biopsy or operative specimens, and in another 13 patients the oesophagus was directly inspected at thoracotomy. In the remaining 17 cases the diagnosis rested upon the continued absence of suspicious clinical, radiological or endoscopic features at follow-up. There was no incidence of a benign peptic stricture undergoing malignant change.

Methods of treatment

The primary objective of treatment was to enable every patient to swallow sufficiently well to maintain his weight and nutritional status, albeit with some modification of diet. Associated oesophagitis was treated by a standard medical régime (Bennett, 1973). Dilatation of strictures was carried out using Neoplex or metal Souttar bougies, usually under general anaesthesia and always under direct endoscopic control, though 11 patients whose stricture demanded repeated dilatation at frequent intervals were taught to pass their own bougies under a local anaesthetic. Fibre-optic oesophagoscopy was not available during the period of this study. The following surgical methods were employed.

Repair of hiatus hernia entailed exposure of the oesophagus within the chest, usually via a left thoracolaparotomy. Reduction of the hernia was achieved as far as possible and the hiatus was repaired by anterior apposition of the crura; routine Heineke–Mikulicz pyloroplasty was carried out additionally.

Operative dilatation of awkward low strictures was performed via a gastrotomy to allow digital dilatation or the retrograde passage of bougies. In a few such cases a Celestin tube was passed from above, right through the stricture and out, to ensure that adequate dilatation had been achieved. In certain selected cases the tube was left *in situ*.

Oesophagoplasty or local plastic repair was reserved for low annular strictures which were exposed within the chest, incised longitudinally through all coats and closed transversely with one layer of interrupted catgut sutures, in a manner akin to Heineke pyloroplasty.

Resection of the stricture was generally performed through a left thoracolaparotomy with direct oesophagogastric anastomosis and the addition of a pyloroplasty. Oblique transection of the stomach allowed the creation of a gastric tube for anastomosis with the transected oesophagus. In 3 cases a segment of jejunum or right colon was brought up to bridge the defect following an extensive resection.

The long term result of treatment in each case was assessed as follows:

Good: Manages virtually normal diet; minimal dysphagia.

Moderate: Careful diet needed; occasional regurgitation of food.

Poor: Liquid diet; frequent dysphagia and regurgitation.

Results of treatment

Of 55 patients presenting with symptoms of reflux, 24 continued to require medical treatment for this after either bouginage or surgery. However, only 3 patients in all had symptoms of reflux aggravated by local treatment of the stricture.

Table III shows that whatever the grading of the stricture at initial endoscopy roughly equal numbers of patients were treated by surgery and bouginage. Though grade I strictures responded readily to simple bouginage, surgery was often required in this group for severe associated reflux oesophagitis. The largest group of strictures belonged to grade II; of these, half were treated surgically and half by bouginage, which usually became progressively easier. Grade III and IV strictures were very unpredictable. Five patients reported some improvement in swallowing despite unsuccessful bouginage, 2 of them requiring no further treatment. Five strictures, initially impassable, subsequently yielded to bouginage, and the long term result in these difficult cases was sometimes surprisingly good. Nonetheless difficulties encountered during bouginage (including previous endoscopic perforation in 3 cases) were a common indication for surgery (*Table IV*) if dysphagia subsequently recurred.

The results of treatment are shown in *Table V*. Thirty-eight patients (46 per cent) were managed by bouginage alone, 17 requiring only one dilatation carried out at the time of diagnostic oesophagoscopy. Where the result remained only 'moderate' after repeated bouginage surgery was advised unless contraindicated by extreme age or infirmity, and these patients comprise the 'bouginage ineffective' group listed in *Table IV*. Forty-five patients were treated surgically (54 per cent) and all but 5 of these had undergone a previous trial of bouginage. Three types of surgical procedure were performed:

1. *Repair of hiatus hernia*

A relatively young group of patients with marked oesophagitis was submitted to anti-reflux surgery with bouginage of the associated grade I or II stricture. This combination was employed in 1 case of grade III stricture presenting in a girl of 14, but the result was poor and she required subsequent resection with oesophagogastrostomy. *Table V* shows that the results of this combined procedure were otherwise very

Table III: GRADING OF PEPTIC STRICTURES

Grade	No. of cases	Treatment	
		Bouginage	Surgery

Table V: RESULTS OF TREATMENT

Procedure	No. of cases	Result			
		Good	Moderate	Poor	Death
Bouginage	38	21	14	0	3
Surgery*	45	32	9	1	3
Repair of hiatus hernia	12	10	1	1	0
Retrograde dilatation	6	5	0	1	0
Oesophageal intubation	9	3	4	0	2
Oesophagoplasty	7	6	1	0	0
Oesophagogastrostomy	12	8	3	1	0
Jejunum/colon replacement	3	2	0	0	1
Total	83	53 (64%)	23 (28%)	1 (1%)	6 (7%)

* In 4 cases more than one type of operative procedure was carried out and the final surgical result is recorded.

Table VI: CASES OF INSTRUMENTAL PERFORATION OF THE OESOPHAGUS

Age	Sex	Difficulty at endoscopy	Delay in onset of symptoms (h)	Level of perforation	Treatment	Complications
70	F	Postcricoid	24	Cervical	Conservative	Nil
77	F	Postcricoid	24	Cervical	Conservative	Nil
88	F	Nil	24	Thoracic	Conservative	Empyema thoracis
37	F	Nil	24	Thoracic	Conservative	Peri-oesophageal abscess
78	F	Grade III stricture	4	Thoracic	Operative	Nil
79	F	Grade III stricture	2	Thoracic	Operative	Death

satisfactory within the period of follow-up, even though extensive peri-oesophagitis often prevented complete reduction of the hernia. The stricture was treated by prior endoscopic bouginage or, in 2 cases, by retrograde digital dilatation at the time of operation. In 3 cases bouginage was required for a short time postoperatively as well.

2. *Limited surgery to the stricture*

Operative dilatation was performed in 6 cases, including 1 man who underwent retrograde bouginage no less than three times in 4 months before obtaining a satisfactory and lasting result. The 1 patient with a 'poor' result had sustained a previous endoscopic perforation and was deemed too frail for any further procedure.

Oesophageal intubation was reserved for a group of very elderly and unfit patients in whom bouginage was inadequate but major surgery impossible. It was not a particularly satisfactory procedure, for 2 patients died and several of the survivors had trouble with the tube. In 3 cases it slipped up the oesophagus to cause renewed dysphagia and require removal. One old lady passed her tube in two pieces per rectum to the consternation of the nursing staff.

Oesophagoplasty was carried out in 7 cases of localized annular stricture close to the cardia (*Figs.* 1, 3). The results were good apart from 1 patient with residual dysphagia due to disordered oesophageal motility. Two patients with anastomotic stricture were treated with equal success by this procedure.

3. *Resection*

Oesophagogastrostomy was carried out in 12 cases; the oldest patient was 72 and all enjoyed reasonable general health. Although several had initial postoperative problems 8 patients obtained a 'good' result. Reflux oesophagitis spoilt the result in 3 cases, aggravated in one by obesity and in another by aspirin. Four patients needed limited postoperative bouginage. The only 'poor' result was in a patient who bled from an anastomotic ulcer, requiring further resection with jejunal interposition. This operation was performed in one other patient (*Fig.* 2) and neither case of jejunal replacement has required any further treatment. The sole case of colonic interposition died following an anastomotic leak on the tenth day, this being the only fatality among the 14 cases of resection.

Complications

Three patients died following endoscopic bouginage, a mortality of 7·9 per cent. The causes of death were pulmonary embolism, chronic chest infection and instrumental perforation. Two patients sustained a limited gastro-intestinal haemorrhage following instrumentation.

There were 6 cases of instrumental perforation of the oesophagus during 270 endoscopies performed for benign stricture, an incidence of 2·2 per cent; the details are shown in *Table VI*. Strangely, 5 of the 6 patients had undergone previous uneventful bouginage. In 2 cases dilatation was completed without suspicion of trauma, in 2 difficulty was encountered at the postcricoid level and in 2 the stricture itself was difficult to dilate. These last 2 both presented within a few hours of the accident and were treated surgically, though in 1 case operation was delayed for 48 hours and the patient died. The other 4 were treated conservatively with intravenous fluids and antibiotics in elixir form. Two of these developed a local abscess but made a complete recovery following drainage; the 2 patients with postcricoid perforation had minimal upset.

The following case report illustrates one remarkable complication of self-bouginage:

> A 65-year-old man presented with dysphagia, epigastric pain and regurgitation of solids. Gross kyphosis was noted. Barium swallow examination showed a large hiatus hernia and an irregular stricture at the cardia with rigid margins suspicious of carcinoma. Endoscopy revealed an inflamed fibrous stricture at 35 cm which could not be dilated; biopsies showed no carcinoma. Ten days later the stricture was successfully dilated. The patient survived a major pulmonary embolus thereafter and his swallowing was much improved. In the following year the stricture was dilated three times and as it remained tight he was taught self-bouginage; this he practised on three occasions, the last time passing a no. 43 FG Neoplex bougie without difficulty. After this he began to develop abdominal pain and was readmitted with a small haematemesis 16 days after self-bouginage. Findings of peritonitis led to laparotomy and the discovery of a large left subhepatic abscess with a second smaller abscess within the liver. These were drained and the patient made an uneventful recovery. Two subsequent attempts at endoscopic bouginage have failed but his swallowing is reasonably satisfactory.

Postoperatively, 3 patients died, a mortality of 6·7 per cent. Two deaths (from haematemesis and aspiration pneumonia respectively) followed insertion of a Celestin tube. The other fatality followed rupture of an interposed segment of colon. There was 1 case of postoperative chylothorax requiring thoracic duct ligation and one of strangulated diaphragmatic incisional hernia.

Discussion

Reflux oesophagitis, the commonest disease affecting the gullet, may eventually lead to peptic stricture in 2–3 per cent of cases (Johnson and Lukash, 1970). Under certain circumstances (Allison, 1970), and especially after any major abdominal operation (Benedict and Gillespie, 1954), this process may develop rapidly; in the present series 3 patients developed an acute peptic stricture, in each case following colonic surgery.

Benedict (1966) advocated bouginage for nearly every peptic stricture, reporting good results in 70 per cent of 133 patients. Many of these with unrepaired hiatal hernia became entirely symptom-free following bouginage. Barrett (1962) objected to simple bouginage on the grounds that it broke down a natural barrier against the upwards spread of oesophagitis, but in the present series reflux was only aggravated in 3 patients undergoing either bouginage or limited surgery to the stricture. Nevertheless, few surgeons would agree with Benedict that haemorrhage and perforation comprise the only indications for surgery. Only 55 per cent of our patients obtained a good result from bouginage alone, and its failure to procure lasting relief from dysphagia was a common indication for operation. Likewise, difficulty encountered during previous bouginage and the possibility of carcinoma will usually demand surgical intervention.

There were 6 cases of instrumental perforation during endoscopy, an incidence of 2·2 per cent, with 1 fatality. Raptis and Milne (1972) reported 4 such cases in their series of 100 benign strictures, again with 1 fatality. The overall incidence of perforation during all upper gastro-intestinal endoscopies is 0·5–0·7 per cent (Elner and Dahlback, 1962; Mark and Knauer, 1969), occurring most frequently in the cervical oesophagus in elderly women (Wychulis et al., 1969). This accident, of which 2 examples are reported here, can usually be managed conservatively (Hardin et al., 1967). Dilatation for benign or malignant stricture is the second commonest cause of iatrogenic perforation (Loop and Groves, 1970). The evidence suggests that patients who present with features of ruptured thoracic oesophagus within a few hours of endoscopy require immediate surgical exploration. The case of silent perforation during self-bouginage is believed to be without precedent, although Goldstein and Sherlock (1966) reported 1 case of unsuspected perforation following endoscopic bouginage carried out under a local anaesthetic.

Endoscopic bouginage is therefore not without risk and in the present series carried a mortality (7·9 per cent) akin to that of operation (6·7 per cent). Furthermore, the 3 postoperative deaths occurred in patients in whom surgery had been necessitated by failure of bouginage. Taken in isolation, the tightness of the stricture was found to be a poor guide in determining the need for surgery. The natural history of peptic stricture appears to be unpredictable and the degree of reflux oesophagitis varies widely between cases. Age and infirmity often preclude the adoption of more vigorous methods of treatment, though it may be a matter of judgement whether multiple bouginage or limited surgery carries a greater risk in such cases. Twenty-one per cent of all cases required no other treatment than a single dilatation of the stricture carried out at the time of diagnostic oesophagoscopy. The policy was therefore to attempt bouginage in nearly every case, but if this should fail, to proceed to surgery, the choice of operation depending upon the degree of oesophagitis and the extent of the stricture.

Where symptoms of reflux overshadow those of stricture lasting relief from dysphagia can usually be achieved by combining hiatal repair with simple bouginage (Hill et al., 1970). Palmer (1968) reported 7 patients treated in this way who subsequently required bouginage as often as those whose hernia had been left unrepaired, but in the present series this was not the case: of 11 patients with early or moderate grades of stricture submitted to hiatal herniorrhaphy, only 3 needed any postoperative bouginage at all and that only for a brief period. This was in spite of the fact that gross peri-oesophagitis often prevented complete reduction of the hernia.

Where the stricture itself is the dominant feature the choice lies between limited surgery and resection. Retrograde dilatation may be of temporary value in the management of an awkward low stricture, especially if there are additional reasons for laparotomy. Intubation is probably best reserved for malignant strictures. Tubes tend to work loose from benign strictures after a time and reflux can be difficult to control (Holden and Wooler, 1971). Oesophagoplasty is a simple and effective method of relieving annular strictures in the lower oesophagus and avoids the need for resection in these cases. Good results were obtained in 6 out of 7 patients and postoperative reflux did not constitute a serious problem.

The troublesome minority of long strictures ('ascending oesophageal fibrosis') will usually demand resection and some kind of oesophageal replacement. Allison (1970) has stated that direct oesophagogastric anastomosis merely reproduces the lesion that caused the original stricture, while Skinner and Belsey (1967) reported a mortality of 14·5 per cent in 106 patients so treated. Twelve cases of oesophagogastrostomy are presented here without operative loss, though 3 of these needed postoperative medical treatment for reflux. Pyloroplasty was routinely performed. Raptis and Milne (1972) omitted this step in 41 oesophagogastrostomies performed for benign stricture and encountered anastomotic strictures in 10 of these. Eight of the 10 were found to have pyloric obstruction and were relieved by a subsequent pyloroplasty.

Interposition of jejunum or colon must add to the morbidity and mortality of resection though it avoids the chance of any future reflux of acid peptic juice. Allison reported excellent results in 50 patients thus treated, with a mortality of only 4 per cent; jejunum was found to be more active than colon in conveying food.

The effect of raising the concentration of potassium in the blood or intestinal lumen on the transport of potassium in the dog intestine

ANNE HARDY-SMITH AND R. SHIELDS*

SUMMARY

The rates of transport of potassium, sodium and water across the intestinal mucosa of Thiry-Vella fistulas of colon and ileum, were studied in dogs in two experimental situations; (1) following intravenous infusion of potassium (15 mEq) over 30 minutes and (2) during variations in the intraluminal concentration of potassium in the range 0·8–16·0 mEq/l.

Following intravenous infusion of potassium the rates of potassium secretion into the colon were usually increased; the rates of sodium and water absorption were either unchanged or decreased. The unidirectional rate of movement of potassium into the lumen increased as the concentration difference across the mucosa increased; the movement of potassium in the opposite direction remained relatively constant. The unidirectional movement of sodium and water into the lumen of the colon also increased but to a lesser extent. The effect on potassium transport in the ileum was not so marked.

With increase in the intraluminal concentration of potassium there was a decrease in the rate of net potassium secretion in both colon and ileum. The rates of net absorption of sodium and water were not significantly altered. Unidirectional potassium movement into the body increased in all the ileal fistulas.

THE intestinal absorption of electrolytes can be influenced by changes in the composition of the body (Shields, 1964; Fordtran and Dietschy, 1966; Vogel et al., 1969; Sladen, 1972). In sodium depletion there is an increased intestinal absorption of sodium and an increased secretion of potassium (Clarke et al., 1967). Similar changes are produced by aldosterone (Edmonds, 1969), whose secretion is known to be increased during sodium depletion (Leutscher and Curtis, 1955; Ross, 1962; Wright, 1962). The secretion of aldosterone is also stimulated by loading the body with potassium (Falbriard et al., 1955; Laragh and Stoerk, 1955; Leutscher and Curtis, 1955; Gann et al., 1964).

However, the effect of potassium overloading on the intestinal absorption of electrolytes is not known. Such knowledge has obvious clinical relevance. Thus, when potassium is being infused intravenously the dose and rate of administration have to be carefully controlled, whereas there appears to be no such restriction when potassium is being given by mouth (Black, 1953). The greater safety of oral potassium may be due to reduced intestinal absorption in addition to its rapid renal excretion as the concentration of potassium in the blood increases.

To study intestinal absorption during potassium loading we used dogs with Thiry-Vella fistulas. As the dogs would not readily eat a diet containing quantities of potassium sufficiently large to raise the body potassium, attempts to produce prolonged accumulation of potassium were generally unsuccessful. However, intravenous infusion of potassium with or without previous dietary administration of potassium resulted in a considerable transient increase in the plasma potassium concentration. This enabled us to study the effects of increasing the blood potassium concentration on the intestinal transport of electrolytes. In addition, the effect of increasing the concentration of potassium in the lumen was studied for comparison.

Materials and methods

Thiry-Vella fistulas of ileum (12–27 cm) or colon (10–13 cm) were prepared in 4 beagles; 2 dogs had a colonic fistula and 2 had an ileal fistula. Three of these dogs were replaced after 18 months; the body weights ranged from 9 to 19 kg.

The dogs were studied over a period of several months under three conditions; control, following rapid intravenous infusion of potassium and during intraluminal potassium administration:

a. Under control conditions the dogs received an infusion of 30 ml aqueous glucose solution (5 per cent w/v) via a cephalic vein at a rate of 1 ml/min immediately before the absorption tests.

b. Following rapid intravenous infusion of potassium. Instead of the glucose solution, 30 ml 0·5 N-KCl (i.e. 15 mEq potassium) were infused at a rate of 1 ml/min. In some experiments the dogs had received a dietary supplement of 240 mEq potassium and 120 mEq sodium per day for either 14 or 28 days before intravenous infusion.

c. Intraluminal administration was carried out in the absence of any intravenous infusion by adding potassium chloride to the basic intestinal test solution to give concentrations of 0·8, 4·0, 11·0 and 16·0 mEq/l of potassium.

Absorption tests, each lasting 10 minutes, were carried out over a period of 5–7 hours using a method similar to that described by Shields et al. (1966). During the period of raised plasma potassium concentration the interval between tests was reduced to 15 minutes to allow more tests to be performed.

After an initial period of rinsing the fistula with modified Tyrode's solution (Code and McIntire,

* Department of Surgery, University of Liverpool.

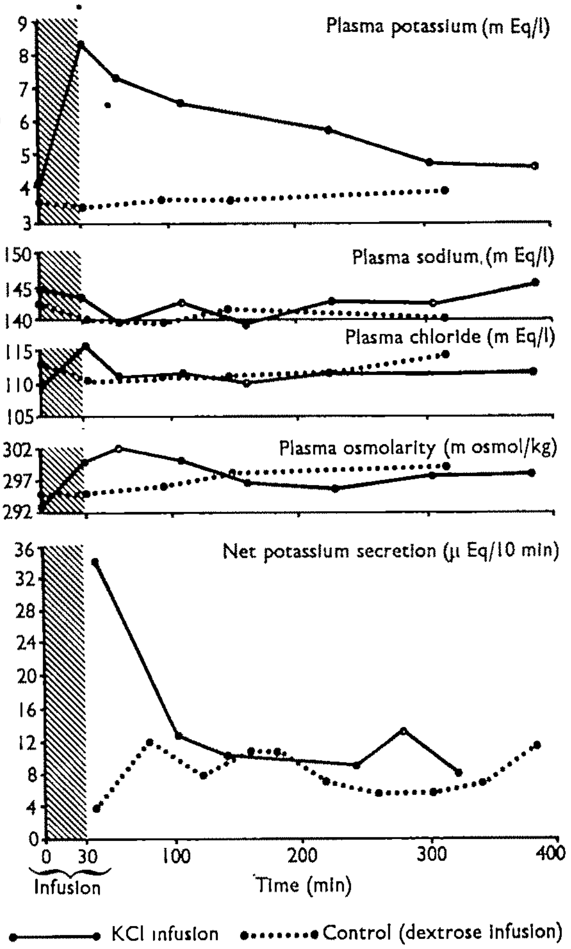

Fig. 1. Changes in the plasma concentration of electrolytes and the net secretion of potassium by the colon in one dog following intravenous infusion of potassium chloride (15 mEq in 30 minutes).

1956) a known volume (20 or 25 ml, depending on the size of the fistula) of the modified test Tyrode's solution containing the radioactive isotopes ^{24}Na and ^{42}K, and the stable isotope deuterium oxide (D_2O, 1 per cent w/v) was installed into the Thiry-Vella fistula. After 10 minutes, as much as possible of the luminal solution was withdrawn and the volume of aspirate measured. Residual test solution in the fistula was measured by rinsing with Tyrode's solution.

Radioactive sodium and potassium in both the rinse and the aspirate were determined by differential counting using a Nuclear-Chicago γ-counter. The volume of residual test solution was calculated from the amount of radioactivity acquired by the rinse. Blood samples were collected before infusion and at intervals after infusion.

Concentrations of sodium and potassium in plasma and aspirate were measured by flame photometry. Concentrations of deuterium oxide in the aspirate were determined by infrared spectrophotometry using the following modification of the method described by Berglund-Larsson (1956). The measurements were carried out in a Perkin-Elmer infrared spectrophotometer, Model no. 177, using universal demountable cells with 0·075 polymeric spacers between quartz windows. A calibration curve was prepared by plotting optical density at 2510 cm^{-1} against atom per cent D_2O over the range 0–1·2 per cent.

The plasma concentration of chloride and the osmolarity were determined using a chloride meter and a freezing point depression osmometer respectively. Packed cell volumes were measured using a microhaematocrit centrifuge.

The concentrations of electrolytes in the red blood cells were measured in the blood samples taken before infusion and in the final sample. The samples were diluted 1 : 1 with standard electrolyte solution (140 mEq/l sodium and 6 mEq/l postassium), frozen overnight, thawed while shaking on a Luckham's Rotatest and then centrifuged at 3500 rev/min. Electrolyte concentrations were measured by flame photometry and the red cell concentrations calculated using the method of Blackmore et al. (1963).

Whenever possible, urine electrolytes were measured by flame photometry in two consecutive 24-hour specimens after the absorption tests. Some of these urine samples were sent to Dr J. C. Davis at the Department of Endocrine Pathology, Liverpool University, for aldosterone determinations using paper chromatography and a double isotope dilution technique (Lund-Johansen et al., 1966).

Total exchangeable sodium and potassium were determined 24 hours after an intravenous injection of ^{24}Na and ^{42}K, 48 hours after the absorption tests.

Calculations

The results were calculated as described by Shields et al. (1966) using formulas derived by Visscher, Vario et al. (1944) and Visscher, Fetcher et al. (1944), and were expressed as rates of transport for the whole Thiry-Vella fistula, i.e. μEq/10 min. Movement out of the bowel into the body is called 'influx', while movement in the opposite direction is called 'outflux'. The term 'absorption' is used when movement into the blood from the intestinal lumen (influx) is more rapid than movement in the opposite direction (outflux). When the rate of outflux is greater than that of influx, the term 'secretion' is used.

Results

1. *Intravenous infusion of potassium chloride*

a. General effects: After rapid intravenous infusion with potassium (15 mEq in 30 minutes) the plasma concentration of potassium increased, and the electrocardiographs of all the dogs showed peaking of the T waves. Results from one experiment are shown in *Fig.* 1. The blood samples obtained within 5 minutes of completing the infusion usually showed the greatest increases in the plasma concentration of potassium, ranging from 3·2 to 5·9 mEq/l. Accompanying these changes was a small decrease in the plasma concentration of sodium and an increase in that of chloride. The plasma osmolarity also increased. There was no significant increase in the concentration of potassium in the red blood cells or in the mean 24-hour exchangeable potassium measured 48 hours after the infusion. The urinary excretion of aldosterone was never observed to be greater than 1 μg/24 h up to 48 hours after the infusion of potassium chloride.

b. Effect on the intestinal transport of potassium:

i. *Colon*: Immediately after the potassium infusion the rate of potassium secretion into the lumen of colon was increased (*Fig.* 1); the rates of sodium and water absorption usually remained within the range observed in the controls.

Increase in the plasma concentration of potassium (without any change in the initial luminal concentration of potassium) will result in an increase in the concentration difference between plasma and lumen. Our results suggested that there was a relationship between this concentration difference and the rate of potassium secretion. We therefore calculated the

correlation coefficients between potassium secretion and the concentration difference. There was a significant negative correlation in 5 out of 8 experiments in the 2 dogs with a colonic fistula (*Table I*). The correlation was negative because rates of secretion are expressed as negative rates of transport.

The correlations between the concentration difference and the unidirectional potassium movements were also examined. There was a significant positive correlation between the plasma/lumen concentration difference and the potassium outflux in 6 out of 8 experiments in the 2 dogs. Thus, the higher the concentration of potassium on the serosal side of the mucosal cell, the greater was the rate of flux of potassium ions into the lumen. There was no consistent correlation between influx of potassium and its plasma/lumen concentration difference.

In one of the dogs some negative correlations were observed between the plasma/lumen potassium concentration difference and the absorption of sodium and water (*Table I*).

ii. *Ileum*: In the ileum there was poor correlation between the plasma/lumen concentration difference and the secretion of potassium (*Table II*). Only 3 out of the 8 experiments in the 2 dogs showed a significant correlation between the rate of potassium outflux and the plasma/lumen concentration difference. Potassium influx was positively correlated with the concentration difference in 4 out of 8 experiments.

There was no significant correlation between the plasma/lumen potassium concentration difference and the absorption of sodium or water in the ileum.

2. *Effect of raising the intraluminal concentration of potassium on the intestinal transport of potassium*

In an initial series of experiments two test solutions with different concentrations of potassium (4·3 mEq/l, and 11·1 mEq/l) were instilled alternately into the intestinal lumen. The results (*Table III*) showed significantly reduced secretion, or increased absorption of potassium, in 3 out of the 4 dogs when the concentration of potassium in the lumen was increased.

These alterations to the net transport of potassium were associated with an increase in potassium influx; potassium outflux did not show any significant change. Net transport of sodium and water was unaltered.

In a subsequent series of two experiments in each dog a range of potassium concentrations from 0·8 to 16 mEq/l were instilled into the lumen. In each experiment 12 absorption tests were carried out with test solutions containing 0·8, 4·0 and 11·0 mEq/l of potassium; 4 tests at each concentration of potassium. A further 3 tests were carried out using a test solution containing 16·0 mEq/l of potassium, giving a total of 15 tests in each experiment. The results are shown in *Table IV*. As the concentration of potassium in the lumen was increased, potassium secretion decreased. There was a significant negative correlation between the rate of net potassium transport and the plasma/lumen concentration difference in 7 of the 8 experiments. There were also significant negative correlations between the plasma/lumen concentration difference and potassium influx in all experiments on the 2 dogs with an ileal fistula, and in 2 of the 4 experiments on the 2 dogs with a colonic fistula. Lower and positive correlation coefficients were observed between the potassium outflux and the concentration difference; these were significant in 6 of the 8 experiments.

The net transport of sodium and water was not significantly changed by raising the concentration of potassium in the lumen of either ileum or colon.

Discussion

The initial increase in the plasma potassium concentration following potassium infusion was limited by the highest concentration of potassium which the dog, and in particular its heart muscle, could tolerate. During this period only a few absorption tests could be performed, because the plasma concentration of potassium fell quickly as a result of its distribution throughout the extracellular space and renal excretion.

An increase in the concentration difference of potassium between the plasma and the intestinal lumen would be expected to increase the transport of potassium down the concentration gradient from the plasma to the lumen, i.e. potassium secretion. This was confirmed in the colon in the present investigation.

More extensive studies of the relationship between potassium transport and the plasma/lumen concentration difference can be performed by increasing the concentration of potassium in the lumen. Under these circumstances there was even better correlation between transport of potassium and its plasma/lumen concentration difference than following the increase in the plasma concentration by intravenous infusion. The luminal concentration of potassium is probably a better estimate of the effective concentration of potassium on the mucosal surface than the peripheral blood concentration is of the effective potassium concentration on the serosal surface.

The rates of unidirectional flux of potassium were also related to the concentration difference between lumen and plasma. When the plasma concentration of potassium was raised, potassium outflux from the colon increased; when the concentration of potassium in the lumen was raised, potassium influx from both colon and ileum increased.

There have been many reports of the good correlation between sodium transport and the sodium concentration difference across the mucosa (Visscher, Fetcher et al., 1944; Curran and Solomon, 1958; Higgins and Blair, 1971; Edmonds and Pilcher, 1972). Sodium absorption increases when the concentration of sodium in the lumen is raised. This is accompanied by an increase in the influx of sodium, but there is no corresponding decrease in the outflux of sodium (Curran and Solomon, 1958; Phillips and Code, 1966; Edmonds and Pilcher, 1972). Results from the present study suggest that potassium behaves in a similar way. In some cases the one-way flux against the concentration gradient was actually increased, although to a lesser extent than the flux down the concentration gradient.

Potassium transport in the colon is usually thought to be passive in nature. Edmonds (1967), who measured potassium net transport and unidirectional fluxes in the rat colon, suggested that potassium influx was by diffusion and that there was no evidence for any exchange diffusion; potassium outflux had two components: active transport and passive diffusion. His results were in agreement with those previously reported by Phillips and Code (1966) in the dog.

The critical concentration of potassium in the lumen is the concentration at which there is no net movement of potassium across the mucosa. The critical luminal concentrations of potassium from the present study are in agreement with those reported by other workers (*Table V*). Phillips and Code (1966) and Edmonds (1967) used the Nernst equation to calculate the luminal concentration of potassium at equilibrium, and showed that the calculated concentrations were in good agreement with the observed concentrations in jejunum and ileum but not in the colon. Similar results were observed by Turnberg (1972); when the critical luminal concentration of potassium approximated to the blood concentration as in the jejunum and ileum, the concentration difference between the plasma and lumen was zero, suggesting that the transfer of potassium occurred by

* Values for ascending and descending colon respectively.

diffusion down a concentration gradient. However, Turnberg suggested that other processes must be involved in the transfer of potassium by the colon, where there was an appreciable potential difference across the mucosa, and the critical luminal concentration of potassium was much greater than the blood concentration. It is therefore important to measure the potential difference across the mucosa in addition to the unidirectional fluxes of potassium for a complete study of potassium transport in the colon. For this reason the value of many investigations, including the present study, is limited.

Following the intravenous infusion of potassium there was no appreciable increase in urinary excretion of aldosterone measured over 48 hours. The potassium concentration in the adrenal artery is known to have a direct effect on aldosterone production, bypassing the normal renin-angiotensin pathway (Dluhy et al., 1972). Aldosterone production may have increased shortly after intravenous infusion but no excess aldosterone appeared in the urine. Further evidence against the involvement of aldosterone in the increased potassium transport observed in the present study was the lack of any significant effect on sodium absorption.

Although we were unable to produce an increase in the total body potassium, we were able to study the effects of increased concentrations of potassium in the plasma and in the intestinal lumen. These increases would be expected to be similar to those following intravenous and oral administration of potassium respectively.

Unfortunately only one of our dogs was used for both series of experiments. In this dog (which had a colonic fistula) there was a much greater increase in potassium secretion into the lumen following a rise in the concentration of potassium in the plasma, compared with the corresponding decrease in secretion following a similar rise in the concentration of potassium in the lumen (unpublished data). Potassium movement into the body from the intestinal lumen appears to be a relatively slow process. This would explain the greater safety of the oral route for potassium administration.

On the other hand, potassium secretion from the body into the intestinal lumen is a more rapid process, and has been used clinically in the treatment of hyperkalaemia by intestinal dialysis (Schloerb, 1958) and using cation exchange resins. The close relationship between the rate of potassium transport by the intestine and the concentration difference across the mucosa would suggest that whenever the concentration of potassium in the plasma rises, potassium secretion into the gastro-intestinal lumen is increased. Aldosterone does not seem to be involved in this transfer which is probably brought about by simple diffusion.

Environmental tests of linear flow ventilation for an operating theatre

THE LATE CHARLES C. SCOTT AND THOMAS D. GUTHRIE*

SUMMARY

Criticisms have been levelled against linear air flow operating enclosures because of their alleged physical and biological conditions and the effects of these, both on the surgical team and on the patient's tissues.

THE relevance of airborne contaminants to wound infection has long been suspected, though direct evidence is lacking. Lister in 1871, by introducing the antiseptic spray to sterilize the air above the incision, took the first practical step to eliminate this hazard, and the present-day operating theatre environment has evolved more as a result of enlightened empiricism than scientific planning.

However, wound infection still occurs, and careful experimental work by investigators in many countries has shown conclusively that the air perfusing the exposed tissues may contain many pathogenic bacteria. The same type of bacteria may also escape into the wound through pinholes in the gloves of the surgeon, or may be contaminating the patient's skin through which the incision is made, and the relative importance of these routes in wound infection is difficult to substantiate. In a classic study by Burke in 1963 it was suggested that as much as 68 per cent of wound contamination is by the airborne route. The relevance of linear flow ventilation to the problem of wound infection is unequivocal. By the use of an enclosure ventilated by this system it is possible, for the first time, to perfuse the surgical incision with air which is, for all practical purposes, sterile. Though sepsis is the crucial yardstick by which a linear flow enclosure will be judged, this evidence will take some time to accumulate. In the meantime it is necessary to evaluate the enclosure on other grounds to ensure that it does not make excessive demands on scarce hospital resources or expose patients and staff to unreasonable hazards.

The enclosure

The operating enclosure is a free-standing structure designed in sections to be erected in an existing theatre (*Fig.* 1). It has the following internal dimensions: 3·05 × 3·66 m, with a ceiling height of 2·74 m. The overall height, which includes the filters and fan units, is 3·55 m. Into the basic sections may be fitted a variety of special equipment as required by the type of surgery to be performed.

General illumination is provided by four fluorescent lamps enclosed in dust-sealed translucent covers. The operating lamp is specially designed for use in operating rooms ventilated by the vertical linear flow system; illumination is from six standard operating lamp units mounted in a low profile frame in such a manner as to give as full a range of movements and as effective illumination as do existing operating lamps. Smoke studies showed that it produces no impediment to the flow of filtered air in the wound area. The ventilation of the enclosure is by the vertical linear flow system, already air-conditioned by the existing theatre ventilation system. The air is forced by powerful fans through disposable pre-filters which remove all particles greater than 5 μ into a plenum, or air chamber, the floor of which is entirely composed of high efficiency particulate air filters (HEPA filters), with a pore size of 0·3 μ. The build-up of pressure in the plenum forces the air through the final filter pores in a myriad of parallel air stream lines all over the room simultaneously, then out via peripheral openings in the walls at floor level.

In the investigations described the enclosure was erected in a disused factory, which was being reconstructed for university purposes. An environment more inimical to tests of air cleanliness could hardly be conceived.

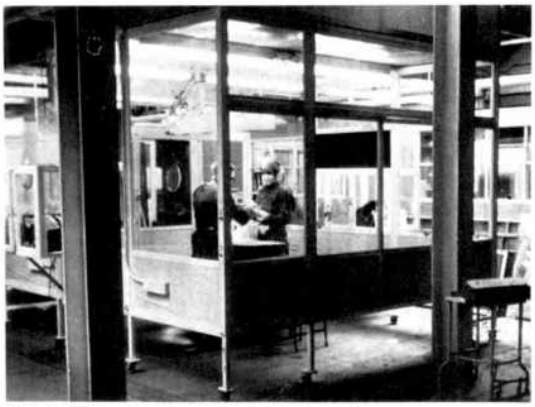

Fig. 1. The free-standing operating enclosure.

Materials and methods

The parameters examined were: (1) air velocity; (2) environmental temperature; (3) tissue drying; (4) air cleanliness, both general and at the incision; (5) noise levels.

1. *Air velocity*

This was measured using a hand-held velometer. By means of a grid, fifteen sampling positions were defined within the enclosure, and the air velocity was measured at three positions; ceiling, head and table height respectively, i.e. 3, 2 and 1 m.

---

* Department of Bacteriology and of Community and Occupational Medicine, University of Dundee.

C. C. Scott died in July 1973 after the tests were completed but before the results were analysed.

2. *Environmental temperature*
The air temperature was measured inside and outside the empty functioning enclosure over a 5-hour period, using a whirling hygrometer to estimate the heat gain from the ventilating and lighting systems.

3. *Tissue drying*
As excessive drying of exposed tissues during surgery would be expected to impair their ability to deal with the local effects of surgical trauma, the impact of the environment on tissues was measured. A whole fresh sheep's liver was obtained from an abattoir. Twelve slices of approximately equal size were cut, each some 9 cm in diameter, so that all the test surfaces were composed of the capsular surface of a lobe. All were weighed on an accurate balance to 0·0001 g and distributed throughout the local environment with equal numbers outside and inside the enclosure. Of those inside the enclosure, half were grouped in the operative area at table height under the operating lamp. Each slice was weighed at half-hourly intervals and the results plotted graphically.

For comparative purposes a similar series of tests was performed in an existing operating theatre ventilated by the turbulent flow system.

4. *Air cleanliness*
The downward flowing stream of clean air might propel contaminants from the head and upper trunk of the surgical team into the wound. A series of tests was designed to quantify total and biologically active particles in this 'critical work site' of the enclosure during a standardized test procedure. For comparison the same tests were repeated in a turbulent flow operating theatre known by previous testing (Scott et al., 1971) to be an efficient one of its type.

In the latter part of the investigation, despite severe theoretical reservations as to the validity of the method, we attempted to enumerate the number of viable particles in the general environment of the enclosure by deploying peripherally situated settle plates on the floor of the enclosure, as described by Charnley (1964).

a. Enumeration of viable particles at the critical work site: To investigate this, a mock incision and a mock operation were devised.

The mock incision was a rectangle of 40 nutrient agar culture plates, each 9 cm in diameter. The total area was therefore 0·56 m^2 and consisted of the whole area of the operating table surface between the two operators (both of whom were fully clothed in conventional theatre garb except for outdoor shoes). The size of the mock incision was chosen to represent a lesion of the whole anterior or posterior surface of the human trunk, e.g. an extensive burn. The exposure necessary for total replacement of the hip joint, which has been much studied in theatre ventilation and is itself among the longer incisions, is approximately one-twentyfifth of this area.

The mock operation lasted 1 hour and was devised to produce repeated arm movements by both operators above the exposed culture plates, and also to oblige them to lean forward repeatedly in both axes of the operating table so that their heads and upper trunk intervened between the illuminated operating lamp and the plates. Each operator took a piece of sterile string from a box at one end of the improvised operating table. The strings were tied together repeatedly, at all times working over the table. After 10 knots, the strings were discarded into a container at the other end of the table. During 1 hour of simulated surgery an average of 500 knots were tied above the mock incision, using hand, arm and trunk movements similar to those used in surgery. The operating lamp was positioned centrally above the table and continuously illuminated. No attempt was made on the grounds of droplet emission to limit conversation which was continuous throughout a rather tedious hour.

Three groups of mock operations were performed in the linear flow enclosure and one in the conventional turbulent flow operating theatre. In the linear flow mock operations the arrangements for each operating session were as follows.

In group 1 the ventilation system was switched on and the enclosure purged for 15 minutes. A set of culture plates was set out on the incision area and systematically uncapped in the direction of the air flow, i.e. from the centre to the periphery. This was found to be a most important detail, and reversing this order invariably led to skin contaminants from the hands lodging on the plates, producing a misleadingly high count. After exposure in the empty enclosure for 1 hour the plates were capped with fresh sterile lids, since lids aggregated together are contaminated on their sterile internal surface by contact with the unsterile outer surfaces of others. The team then gowned up in the enclosure with the ventilation system in operation, and a set of fresh culture plates were exposed in a similar fashion. At the end of the mock operation the plates were capped as before and a fresh series displayed. The ventilation system was then switched off and another mock operation performed.

In group 2 one set of test plates was exposed in the unventilated enclosure, a second set during a mock operation without ventilation and a third set during a mock operation with the ventilation system in action.

In group 3 the procedures were exactly the same as in group 2 except that after the mock operation without ventilation the team changed their sterile gowns, caps, masks and gloves for the operation with the ventilation switched on.

In group 4 the locus was the turbulent flow ventilated operating theatre. One set of plates was exposed in the empty theatre and a second set during a mock operation.

b. Enumeration of total particles: The sampling tube of a Royco automatic particle counter protruded through an aperture in the base of a mock incision so

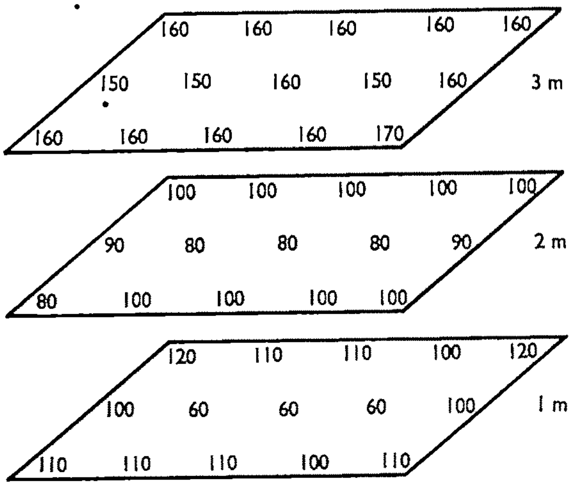

Fig. 2. Linear air flow velocities (ft per min).

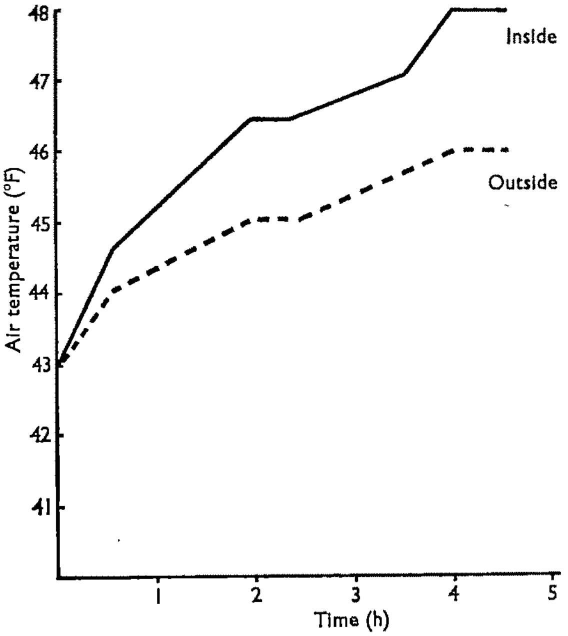

Fig. 3. Environmental temperature.

that the total particle count could be recorded throughout the test period. As the emission, removal and recording of particles are all on-going activities they are illustrated by a range rather than a mean. The Royco particle counter was unavailable at the time the group 4 tests were carried out.

c. *Enumeration of viable particles in the general environment*: Twelve culture plates on the floor at the periphery of the enclosure were uncapped while mock surgery was in progress and remained exposed for 50 minutes. They were then capped and treated similarly to the mock incision plates.

d. *Spatial distribution of the viable particles*: As the distribution of the biologically active particles shed during simulated surgery within the linear flow ventilated enclosure was considered to be of equal importance to their number and identity, all the culture plates were numbered and always arranged in the same order on the operating table. The positions of the two operators were also constant.

e. *Identity of biologically viable particles*: It had been intended to identify all such particles at least to generic level, but this proved impossible in practice because of the very high contaminant counts in the unventilated enclosure and in the turbulent flow operating theatre. In the linear flow ventilated operating enclosure, particular attention was devoted to the examination for *Staphylococcus aureus* as an index of possible human contamination from the team.

All bacterial colonies were examined by Gram's stain. If coccal in morphology, they were tested for catalase and tolerance to salt by subculture on to 6 per cent salt agar for 1 week at 37 °C. If growth occurred they were inoculated into boiled and cooled tubes of Hugh and Liefson's media to disclose fermentative or oxidative properties. If the former, a tube coagulase test was performed.

5. *Noise levels*

The sound pressure levels were recorded using previously calibrated Bruel and Kjaer portable sound level meters (type 2203), incorporating an octave band filter set (type 1613).

Results and discussion

Air velocity (*Fig.* 2)

The velocity of the vertical air flow was found to be less uniform over all the enclosure than had been predicted. It is possible that a contributory cause of this may have been the very considerable number of demonstrations performed using dense clouds of smoke, which may have adversely affected the filter material, although almost certainly defects in the design of the plenum and the enclosure were the main causes. Slight modification of the specifications of the ventilating system can rectify this. Though the velocity of the vertical air flow in the central area was only two-thirds of its design value, smoke tests showed a good flow from the centre of the table to its periphery, and the loci of the viable contaminants at the mock incision confirmed this.

Environmental temperature (*Fig.* 3)

Over a 5-hour period in the empty functioning enclosure a rise of some 1·2 C degrees, relative to the external temperature, was found. A similar series of observations performed within an existing operating theatre confirmed that its air-conditioning system maintained the temperature at 23 °C, compensating for changes in the external temperature, though these were less than 0·6 C degree during the test period. As the linear flow enclosure has no temperature-regulating mechanism and is designed to be used in an existing theatre equipped with these facilities, it does not appear that the heat generated by its use is beyond the regulative capacity of such a system.

Tissue drying (*Figs.* 4, 5)
In the enclosure there was a 3 per cent loss over 4 hours, while in the theatre the corresponding loss was 6 per cent. This suggested that the heat of the theatre lamp was the main cause of the much greater effect in the existing theatre. Though all the tests in the linear flow enclosure were performed at lower environmental temperatures, it should be noted that the light source of the linear flow lamp is identical with that of the theatre lamp. Special features of its design, however, enable it to utilize to the full the cooling power of the greatly increased air turnover of 600 air changes per hour, compared with 20 in the existing theatre. As temperatures in the theatre require the exposed tissue to be irrigated with saline as a routine procedure, these tests do not suggest that the linear flow enclosure is at a disadvantage in this respect.

Air cleanliness (*Tables I, II*)
The total viable particles deposited over 10 hours of mock operating under linear flow ventilation (*Table I*) are seen to have settled on the outer agar plates, i.e. well away from normal-sized incisions.

Performing a mock operation under linear flow ventilation resulted in an average of 6 viable particles per hour being deposited on the 0·6 × 0·9 m mock incision, whereas with no ventilation the viable particulate deposition was increased by a factor of approximately 100 (*Table II*, group 1). Performing a mock operation under linear flow ventilation wearing the same gown etc. as had been used during a mock operation without ventilation increased the deposited viable particulate from an average of 6 per hour to an average of 32 per hour (*Table II*, group 2). The change of gown, cap and mask prior to carrying out a mock operation under linear flow conditions, after performing a mock operation with no ventilation, decreased the viable particle contamination at the work site (*Table II*, group 3). This could be explained by the fact that when no change of clothing was made viable particles adhering to the protective clothing were being flushed off. The deposited viable particles under turbulent flow conditions showed no marked change between an empty theatre and similar conditions with a mock operation being performed (*Table II*, group 4).

As no viable particles were observed in the settle plates situated around the perimeter of the linear flow enclosure, it would appear that the velocity of air passing horizontally outwards around the lower edges of the enclosure is sufficiently high to entrain the viable particulate matter.

Noise levels (*Fig.* 6)
The noise level with all three fans operating is considerably higher than the recommended level for hospitals which is NC 30. Reduction of noise could be

achieved by installing quieter running fans and by positioning noise-insulating baffles between the fans and operating team.

Conclusions

This series of tests has shown that many of the fears expressed regarding the conditions to be found in linear flow ventilation in an operating theatre are unfounded.

Changes in temperature were within the regulating capacity of the conventional air-conditioning plant of the theatre within which the enclosure would be installed.

The chief cause of drying of exposed tissue was heat from the theatre lamp, and this was not affected significantly by the increased air flow. The introduction of particulate-free air directed downwards over the patient and operating team at a flow rate of 60–70 linear feet per minute reduced the total particulate matter deposited at the critical work site by a factor of 100.

Most of the surgeons to whom the enclosure was demonstrated showed great interest in the benefits to be expected from its use. Despite the high air turnover (600 air changes per hour), almost all commented on the lack of sensation of air movement and the moderation of the noise level, which they had expected to be excessive.

Bilateral idiopathic parotid duct strictures

M. ADISESHIAH*

SUMMARY

Details of 2 patients with idiopathic bilateral parotid duct strictures are presented. The possible aetiology and treatment are discussed.

OBSTRUCTION of Stensen's duct has been attributed to calculus, neuromuscular incoordination, stricture, foreign bodies, mucous plugs and trauma from erupting teeth or ill-fitting dentures (Barsony, 1925; Rose, 1954; Patey, 1965). Two patients have recently been seen with bilateral strictures of the parotid duct in which there was no obvious causative factor. No reports of similar cases have been found in the literature.

Case reports

Case 1: A 43-year-old Asian male presented in April 1973 complaining of intermittent bilateral parotid gland swelling of 1 year's duration. The swelling caused him discomfort; he had learned to massage his glands when swollen and this would result in a gush of saliva inside his mouth with resultant relief of his discomfort. Physical examination revealed a fit young man. Both parotid glands were slightly distended and tender. The teeth, gums and orifices of the parotid ducts looked normal. The patient was able to demonstrate the emptying of his parotid glands by massaging. A gush of saliva appeared at the duct orifice. Subsequently the gland felt normal again.

Plain X-ray of his parotid glands and ducts did not reveal a calculus. Parotid sialography was performed and a film of the right side is shown in *Fig.* 1. There is a narrowing of the terminal 2 cm of the parotid duct. Proximally there is uniform dilatation of the main duct, but the small ducts and acini appear normal. Similar changes were found on the left side.

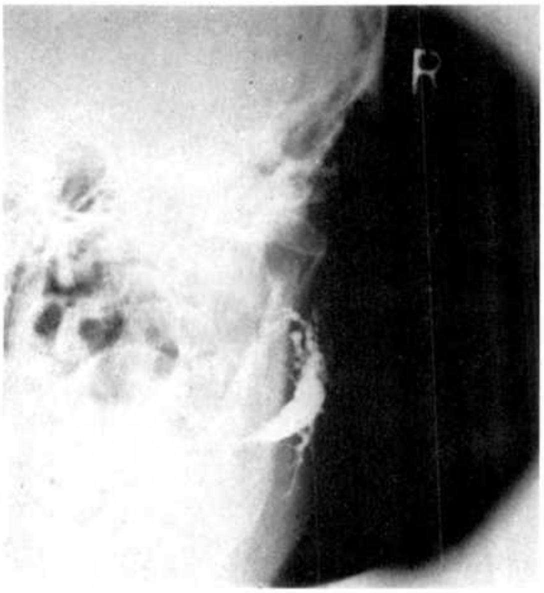

Fig. 1. *Case* 1. Right parotid sialogram showing dilatation of the main duct only with narrowing of the terminal portion.

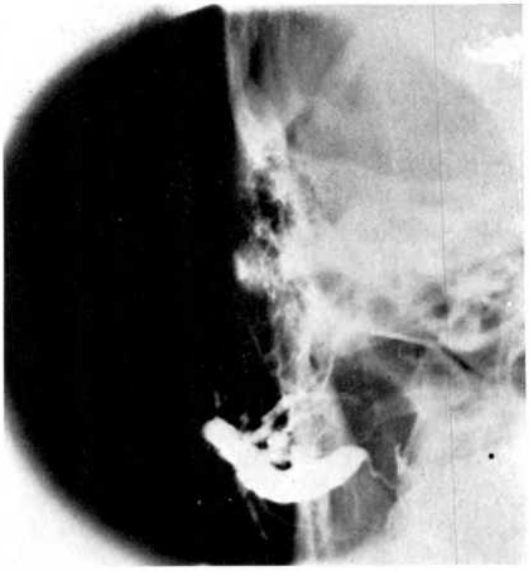

Fig. 2. *Case* 2. Left parotid sialogram showing dilatation of the main duct only with narrowing of the terminal portion.

Case 2: A 29-year-old Asian female presented in October 1972 complaining of intermittent painful bilateral parotid swelling of 1 year's duration. The pain and swelling were invariably present on rising in the morning, and 2–3 hours later there was a sudden gush of saliva accompanied by relief of the pain and swelling. Physical examination revealed a fit young woman with slightly tender swollen parotid glands. The teeth, gums and orifices of Stensen's duct were normal. When the gland was massaged there was a sudden gush of saliva through the orifice with deflation of the gland on that side. The parotid sialogram of the left side is shown in *Fig.* 2. The terminal 0·5 cm of duct is narrow and the proximal part of the main duct is dilated. The small ducts and acini appear normal. Similar changes were seen on the right side.

The patient was treated by dilatation of the terminal portion of the duct with lacrimal duct dilators 3 and 6 months after presentation, but her symptoms remained unchanged.

Subsequently she underwent parotid terminal dochoplasty in which the termination of the parotid duct was slit open up to the dilated portion. The strictured portion was resected on each side and submitted for histological examination. The duct mucosa was sutured to the buccal mucosa with interrupted 4/0 plain catgut sutures. The final result immediately after surgery is shown in *Fig.* 3.

On histological examination both strictures showed an essentially similar nature. The normal pseudocolumnar epithelial lining had undergone squamous metaplasia, deep to which was dense fibrosis with collections of chronic inflammatory cells (mainly lymphocytes and macrophages) without any specific features. No microcalculi or mucous plugs were seen, or any iron pigment which might have indicated previous trauma. This is illustrated in *Fig.* 4. In contrast, *Fig.* 5 shows the appearance of a normal parotid duct (obtained from a 56-year-old man at autopsy). Pseudocolumnar epithelium overlies a narrow zone of loose connective tissue with little

---

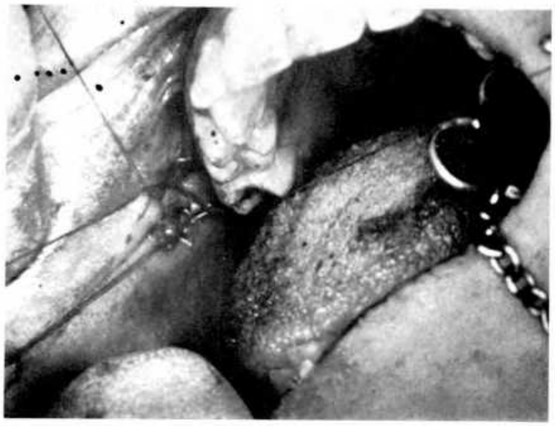

Fig. 3. *Case* 2. Appearance of new right duct orifice at the completion of dochoplasty.

collagen and of scanty cellularity, outside which is buccinator muscle.

Ten days after operation the patient suffered an attack of pain in each parotid region. This was thought to be due to infection and responded well to systemic antibiotic treatment. Ten months after operation she was pain-free. There was a free flow of saliva from each duct orifice.

Discussion

Barsony (1925) described a case of idiopathic bilateral parotid duct obstruction. He suggested that obstruction may be due to neuromuscular incoordination which would result in the main duct failing to release saliva. The lesion may be similar to that seen in the oesophagus in achalasia or in the colon in Hirschsprung's disease. However, in our second patient there was histological evidence of fibrotic stricture.

Rose (1954) described a 'papillary' variety of parotid duct stenosis. This occurred in young people, normally at the time of eruption of the third molar tooth. Food is chewed on the opposite side of the mouth with resultant trauma to the orifice of Stensen's duct on that side. In our patients the onset of symptoms was unrelated to eruption of the wisdom teeth or indeed to trauma. Further, in our patients the condition was bilateral. All of Rose's patients' symptoms cleared up after one or two dilatations, whereas the symptoms of the present *Case* 2 were unrelieved by two dilatations at an interval of 3 months.

Patey (1965) has shown that ductal obstruction may be caused by mucous plugs, the mucus being secreted by glands in the parotid gland and duct itself. However, the sialographic and histological appearances in our patients were not characteristic of the disease that Patey described.

Patey mentioned the triad of obstruction, depression of secretion and infection acting in a viscious cycle that might cause strictures, but in our patients there was no evidence of infection or of diminution of salivary flow. The gush of a large quantity of clear saliva produced on massaging the glands was easily demonstrable. The salivary gushing was recorded on 16-mm moving cine film in *Case* 2 prior to

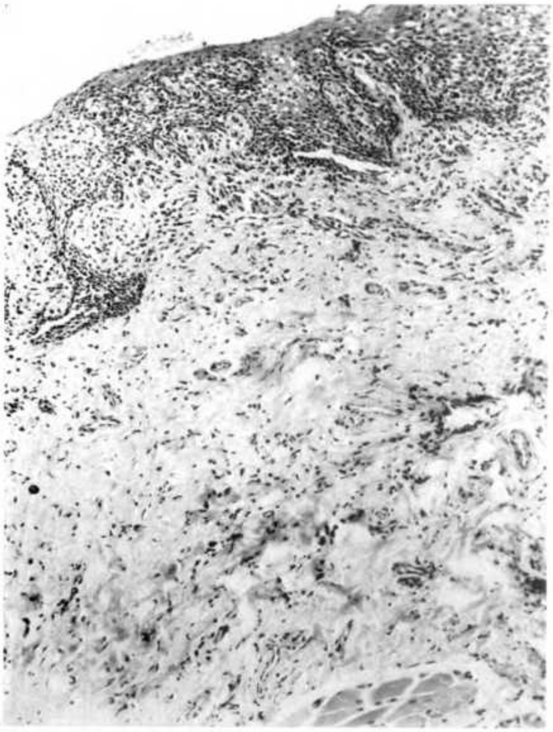

Fig. 4. *Case* 2. Histology of the right parotid duct stricture. Note the dense fibrous tissue extending from the metaplastic squamous epithelial lining to a bundle of skeletal muscle fibres (buccinator). HE. (× 75.)

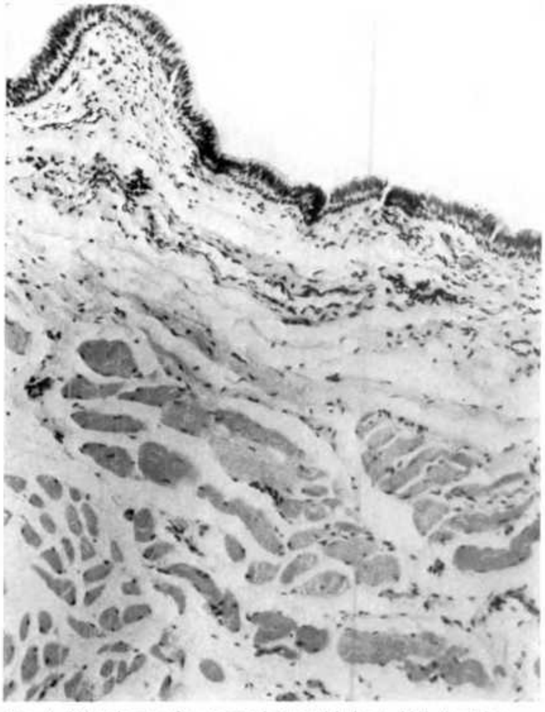

Fig. 5. Histology of a normal parotid duct. HE. (× 75.)

dochoplasty. In recurrent parotitis the secretion is usually viscid, scanty and sometimes contains pus and debris.

The symmetrical nature of the disease suggests that there may be a constitutional and/or dietary factor involved. Both patients rarely chew betel nut and clinically there was no evidence of submucous fibrosis. However, it is possible that a constituent used in spices in Indian cooking may be responsible.

Case 1 obviously required no treatment, having learned to massage his glands and thereby empty them. *Case* 2 was unrelieved by dilatation and had been unable to empty the glands by massage. Hence parotid terminal dochoplasty was performed. This was followed by immediate relief of symptoms; she had one episode of infection which responded to antibiotic therapy. Subsequently she became symptom-free. A possible complication in the long term is the development of ascending parotitis. Prophylactic measures against this include adequate hydration at all times and the use of sialogogues (e.g. citrous-flavoured sweets).

Acknowledgements

My thanks are due to Professor C. G. Clark and Mr D. A. Bailey for allowing me to report on their patients. I would like to express my gratitude to Mr M. J. Hobsley for discussing the problem of idiopathic parotid duct obstruction and to Dr P. M. Sutton and Dr C. Fisher for help with the histology.

Your hands are your most important instruments-
it pays to take care of them

The obvious fact that a surgeon's hands are of prime importance to his work was borne in mind when 'Hibiscrub' was formulated. 'Hibiscrub' is designed to keep hands healthy, even after repeated use.

However, the prime importance of a handwash is effectiveness: rapid prolonged bactericidal action against skin bacteria is assured by the presence of the well-proven antiseptic 'Hibitane'.

"These studies have shown that a 4% chlorhexidine detergent solution ['Hibiscrub'] is a potentially outstanding addition to the small list of detergent-disinfectant preparations for the hands of surgeons and nurses, with a greater immediate effect than that obtained with the hexachlorophane or even the iodophor preparations."
British Medical Journal, (1973), 1, 510.

General anaesthesia during early pregnancy

LEO STRUNIN, K. KNIGHTS, J. M. STRUNIN
AND MICHAEL E. WARD*

SUMMARY

General anaesthesia in the early stages of pregnancy may carry an increased risk of embryotoxicity. One hundred and six women scheduled for non-emergency surgery were interviewed preoperatively and their menstrual history taken. Forty-three (41 per cent) were considered to be using adequate contraceptive therapy. Thirty-one (29 per cent) of the patients could have been in the early stages of pregnancy, and of these women, 19 (61 per cent) were undergoing surgery of a minor nature. Simple history taking identified the women 'at risk' and it is suggested that surgery could have been delayed without detriment in many cases.

IT is generally believed that anaesthesia and surgery during early pregnancy carry some risk of spontaneous abortion. The advice usually given, based on clinical experience, is that where surgery is necessary it should be delayed if possible until the second trimester. Animal studies (Smith et al., 1965; Fink et al., 1967) have shown that all the commonly used volatile anaesthetics can cause spontaneous abortion and fetal abnormalities when administered during early pregnancy. The concentrations used in these studies have always been of the order of those during general anaesthesia. Recently, concern has been expressed regarding a possible correlation between low concentrations of volatile anaesthetic agents in the atmosphere of operating areas and the incidence of spontaneous abortion and fetal abnormalities among female operating room personnel (Askrog and Harvald, 1970; Cohen et al., 1971; Knill-Jones et al., 1972). It should, however, be made clear that the evidence for this correlation is entirely circumstantial (Spence, 1973), and the effect of either low or anaesthetic concentrations of volatile anaesthetics in early pregnancy in humans is unknown. It seems that the greatest risk is probably during the early weeks of pregnancy (Shnider and Webster, 1965).

It is not common practice to inquire into a woman's menstrual history prior to general anaesthesia other than for gynaecological surgery. It may be, therefore, that women are exposed unnecessarily to potentially embryotoxic drugs during the earliest stages of pregnancy, indeed before pregnancy is diagnosed. The present study was undertaken to establish the population 'at risk' of undergoing general anaesthesia while pregnant.

Patients and methods

One hundred and six women of childbearing age (14–45 years), scheduled for non-emergency surgery, excluding gynaecology, were visited by one of the authors preoperatively (*Table I*). The patient's menstrual history was taken and the following information obtained:

1. Whether menstrual periods were regular or irregular.
2. The duration of each menstrual period.
3. The interval between menstrual periods.
4. The date of the last menstrual period.
5. Whether they were taking oral contraceptives.
6. Whether there was any chance of pregnancy.

In addition, the nature of the operation to be performed was recorded.

Table I: PREGNANCY RISK GROUPS

Groups		No. of patients		%
Effective contraception				
Oral contraception	32		30	
Hysterectomy	6		6	
Tubal ligation	4		4	
Intra-uterine contraceptive device	1		1	
		43		41
'Pregnancy unlikely'		32		30
'Pregnancy possible'		31		29
	Total	106		

Table II: INTERVAL BETWEEN CALCULATED DATE OF OVULATION AND GENERAL ANAESTHESIA IN 'PREGNANCY POSSIBLE' GROUP

Interval: 10 wk	No of patients: 2
6–9 wk	1
4–5 wk	2
2–3 wk	4
10–13 d	4
5–9 d	3
1–4 d	14
Total	30*

* Pregnancy had been confirmed in 1 patient not included here.

Results

Of the 106 women studied, 43 (41 per cent) were considered to be using adequate contraceptive therapy: 32 (30 per cent) were taking oral contraceptives; 6 (6 per cent) had had a hysterectomy; 4 (4 per cent) had had tubal ligation and 1 had an intra-uterine contraceptive device. Of the remaining 63 (59 per cent) patients, 32 (30 per cent) were calculated on the basis of their menstrual history to be between their last period and ovulation ('pregnancy unlikely' group). Thirty-one (29 per cent) patients were considered to be at risk (*Table II*), since they were at a point in their menstrual cycle where they could have conceived prior to hospital admission ('pregnancy possible' group).

Total	43	32	31	106

On direct questioning, one of the 'pregnancy possible' patients was aware that she was pregnant, but she had reached 28 weeks' gestation and was having an excision of a breast lump. Four other women conceded that they might be pregnant. For 5 patients it was 7 or more weeks since their last period, but of these, one was 15 years of age and her previous period had been her first; 2 others had only within the past 8 weeks terminated regular oral contraceptive therapy. A 27-year-old woman about to undergo dental extractions had waited 10 weeks since her last period and admitted concern that she might be pregnant. However, a pregnancy test performed within the past 5 days was negative. There were 5 other women where more than 4 weeks had elapsed since their last period; of these, one had been in hospital continuously during this time.

Table III shows the operative procedures carried out in the 106 women studied. It can be seen that of the 31 women in the 'pregnancy possible' group, 19 (61 per cent) were undergoing operations of a minor nature which could have been postponed.

Discussion

We have been unable to find any authoritative statement in the world literature concerning the number of pregnant women undergoing anaesthesia. From our investigations, however, it seems clear that women who know or suspect that they may be pregnant have a natural anxiety concerning anaesthesia and surgery. Furthermore, 26 of the 106 women in our series could have been pregnant without being themselves aware of the fact. There are no absolute means of establishing beyond doubt whether or not these women were in the early stages of pregnancy, although more detailed questioning would probably have eliminated a proportion. There are, of course, a number of tests which may be applied. Of these, the Pregnosticon (Organon) or Gravindex (Ortho Pharmaceuticals Ltd) test is the simplest, involving the application of a drop of urine to a slide preparation. An answer, given by the presence or absence of agglutination, is available within 3 minutes. Unfortunately, although only few false positive results are produced there are generally an appreciable number of false negatives. In cases of pregnancy a reliable positive result will not be obtained until 4 weeks after ovulation. This will, therefore, preclude the use of this technique to exclude patients in the very earliest stages of pregnancy when the fetus may be at greatest risk from anaesthetic agents. For this reason such urine testing was not carried out on patients in the present study. Other more sensitive pregnancy tests such as progesterone assay (Yousefnedjadian et al., 1972) or human chorionic gonadotrophin assay (Wide, 1969) are available and will give reliable results after the seventh day following ovulation, but these techniques are slow, expensive and restricted at present to a few research centres. *Table II* shows that even these most sensitive tests of pregnancy would leave more than 14 (45 per cent) of the 31 patients in the 'pregnancy possible' group undetected at the time of anaesthesia and surgery. Therefore, routine testing for pregnancy would not, at present, identify the patients in the earliest stages after conception. Where some departure from a previously regular menstrual cycle draws attention to the possibility of pregnancy, one of the routine pregnancy tests should be carried out, and there may be a case for deferring surgery, where possible, until a conclusively negative result is obtained.

It is regrettable that it is not common practice to ascertain a woman's menstrual history prior to anaesthesia and surgery. It is clear that simple unembarrassing questions can identify a woman who may possibly be pregnant. Since many of the operative procedures were of a non-urgent simple nature, it would seem feasible to delay surgery until the potential risk of pregnancy had passed.

An interesting point concerning the women taking oral contraceptives relates to their anxiety regarding taking their pills in relation to an operation. There seemed to be no clear advice as to whether they should take the pill in the immediate preoperative period and what should be done if they were unable to resume oral contraceptive therapy immediately postoperatively. Our gynaecological colleagues advise us that the correct management should be that where only 1 day is missed it can be compensated for by taking an additional tablet the following day. If 2 or more days are missed, then the advice should be to discontinue oral contraception for 5 days and then commence a new course. It is of course obvious that during the interval conception is possible.

Despite the commonly held view that anaesthesia and surgery should not be carried out during the early stages of pregnancy, our study shows that a substantial number of women who could be pregnant are in fact put at risk. Simple history taking can identify these women, and again our study shows that many of them are scheduled for non-urgent surgical procedures. There may, therefore, be a good case, in the light of the existing evidence concerning embryotoxic effects of volatile anaesthetics, to delay surgery in these instances.

Acknowledgements

The authors would like to thank their surgical colleagues for permission to interview their patients preoperatively, and Mr Julian Elias of the Department

of Obstetrics and Gynaecology, King's College Hospital, for help and advice.

Renal transplantation in the unimmunosuppressed pig: an abnormal response

JOHN TERBLANCHE, ROSEMARY HICKMAN AND C. J. UYS*

SUMMARY

A series of 82 kidney allografts and autografts in unimmunosuppressed pigs surviving for longer than 5 days has been compared with a previously reported series of 24 unimmunosuppressed pig kidney allografts. In the previous series 40 per cent survived for longer than 20 days. In the present series only 2 per cent of 55 transplants performed in cross-bred pigs obtained from different farms survived for longer than 20 days. The major causes of death were unrelated to rejection, principally gastric ulcer bleeding. In the further 16 transplants between different pure-bred animals (thereby ensuring genetic disparity) the ulcer incidence was lowered by a gastro-enterostomy, and 12 per cent survived for longer than 20 days. Histological assessment of rejection in the latter group revealed 20 per cent with minimal rejection, and 60 per cent in which rejection was considered insufficient to account for the death of the animals. Based on the evaluation of 95 unimmunosuppressed pig kidney allografts in both series, it is concluded that a wide and unpredictable range of survival time occurs. Therefore the pig kidney allograft model is an unsatisfactory model in which to study immunosuppressive régimes. Also the unimmunosuppressed pig appears to show less evidence of kidney allograft rejection than the dog, irrespective of genetic disparity. It is tentatively suggested that this might be a lesser manifestation of the unexplained phenomenon of minimal rejection of liver allografts noted in unimmunosuppressed pigs.

IN a previous paper a series of 24 kidney allografts in unimmunosuppressed pigs was reported. Survival in 40 per cent of these animals was longer than 20 days and in 25 per cent longer than 40 days (Terblanche et al., 1973). On the other hand, skin allografts were rejected normally. This and earlier reports documented protracted survival following liver transplantation in the unimmunosuppressed pig (Dent et al., 1971a; Spilg et al., 1971; Spilg et al., 1972). We have also suggested that the pig is unique in its ability to tolerate vascularized organ allografts (Terblanche et al., 1973). Reports from other laboratories have shown the immunological effect of pig liver allografts, resulting in prolonged survival of simultaneous transplants of skin or kidneys (Calne et al., 1969), and the potentiating effect of portal venous drainage on pig kidney allografts (Mazzoni et al., 1971).

It has also been reported that the pig cellular immune response is more susceptible to modification than that of other animals (Perper et al., 1971). These findings require further elucidation and are at present being investigated in detail in our laboratory. The first phase of the investigation was a detailed study of unimmunosuppressed pigs with kidney allografts which is reported in this paper. In some pigs, biopsies were performed at 10 days, and the histology compared with subsequent autopsy specimens, since a reduction in the cellular manifestations of rejection had been noted in serial biopsies from unimmunosuppressed liver transplants (Dent et al., 1971a). A small series of autografts was also performed to investigate the biochemical and histological response to the transplant procedure itself, and to act as a control for the allograft experiments. Previous studies have shown that some features possibly attributable to rejection in unimmunosuppressed pig liver allografts also occur in autografts, and may be due either to the operation or to subsequent complications, especially infection (Dent et al., 1971a).

Materials and methods

Kidney allo- and autografts were performed in 100 unimmunosuppressed pigs weighing between 15 and 20 kg and aged between 35 and 50 days. Only the 82 pigs which survived longer than 5 days have been included in the analysis, as the 18 earlier deaths were due to technical failures. *Table I* shows the experimental design. Eleven autografts (group A) were performed to obtain baseline control data. The 71 allografts were divided into group B (55 experiments) where cross-breed Large White/Landrace pigs obtained from different farms were used, and group C (16 experiments) where different pure-bred pigs were used as recipient and donor in each experiment in an attempt to ensure genetic disparity. A gastro-enterostomy was performed in the last 9 pigs in group B and all the animals in group C in an attempt to reduce the incidence of bleeding gastric ulcers (unpublished data).

Anaesthesia and drugs

All the animals were given a commercial feed ('creep' meal) until the day before operation and then starved for 24 hours preoperatively, with access only to water (Dent et al., 1971b). Anaesthesia was induced with halothane, and maintained through an endotracheal tube with oxygen, nitrous oxide and halothane given by intermittent positive pressure ventilation. A catheter was inserted into the external jugular vein and used to administer 300–400 ml Ringer's lactate in 10 per cent invert sugar intraoperatively and to obtain

postoperative blood samples. During the operation each animal was heparinized with 2 mg/kg and received 0·5 g chloromycetin and 600 mg crystalline penicillin, as well as 2 mg furosemide to stimulate urine flow, and 100 mg sodium bicarbonate during the period of aortic clamping to compensate for the associated metabolic acidosis. No blood transfusion was administered. In addition, in 19 animals in group B (i) iron–dextran complex was administered intravenously in an attempt to prevent the anaemia noted in previous allografts.

The donor procedure

A similar operative technique to that described in 1971 by Golby and White was used with several specific modifications. Two pigs were anaesthetized simultaneously in the allograft experiments, each donating its left kidney for orthotopic transplantation.

Using full sterile precautions, the abdomen was opened through a long midline incision. In each pig a right nephrectomy was performed and this kidney discarded. The left renal artery was dissected out to the aorta and the renal vein dissected beyond the confluence of tributaries to ensure an adequate lumen for anastomosis. Care was taken to preserve the lumbar artery and vein which branched from the aorta and renal vein at this site. Ligation of the lumbar artery resulted in hindlimb paralysis in 3 pigs, as also reported by Golby and White, while careless incision of the lumbar vein at the time of kidney removal led to problems in subsequent venous anastomosis. The nerves around the aorta were preserved where possible, as severance appeared to be a contributing factor in hindlimb paralysis. In most cases the large lymph ducts around the aorta were opened during dissection.

After heparinization, the kidney was removed, taking a Carrell patch of aorta with the renal artery and leaving a defect in the aorta which was cross-clamped above and below the site. The kidney was submerged in cold saline without perfusion. The kidney ischaemia time (*Table I*) depended upon the availability of one or two surgical teams for the allografts. Where both transplants were performed by one operator, one kidney was immersed in saline at 4 °C until the first procedure had been completed, and was then transplanted into the other pig (long ischaemia time). This was simulated in 4 of the autografts.

The recipient procedure

The donor kidney was placed in the left renal fossa. The renal artery was anastomosed to the defect in the recipient aorta using the Carrell patch with continuous 4/0 silk, and a direct renal vein to renal vein anastomosis was performed with continous 5/0 silk. Mean renal ischaemia times ranged from 26 to 61 minutes (long or short ischaemic time groups as shown in *Table I*). A direct ureter to ureter anastomosis was performed just below the renal pelvis using interrupted 6/0 silk. In most instances the branch from the renal artery to the upper ureter was preserved with the donor kidney. Urine excretion usually commenced immediately. In the animals in group B (ii) and group C an anterior gastro-enterostomy was performed using two layers of 3/0 catgut in an attempt to prevent gastric ulceration. The posterior peritoneum over the kidney was closed with 2/0 catgut and the abdomen closed in layers with 0 chromic catgut and a subcuticular nylon suture.

Postoperative course

All the animals received intravenous infusion for 24 hours and then recommenced oral feeding. The antibiotics (chloromycetin and pencillin) were continued for 5 days, and blood samples were taken for a week, thereafter at 10 days and then at weekly intervals. Renal biopsies were performed as an open procedure under minimal halothane anaesthesia between 9 and 11 days postoperatively in 18 animals in groups A and B (*Table I*). A full autopsy was performed as soon as possible after death, but always within 18 hours.

Results

Survival

A review of the allografts in groups B and C (*Table I*) showed that neither differences in ischaemic interval nor the addition of a gastro-enterostomy altered the mean survival time in this group of unimmunosuppressed pigs. The survival times of the present allografts have been compared in *Table II* with a previously reported group of 24 unimmunosuppressed pigs of the same or different breeds in which surprisingly prolonged survival was obtained (Terblanche

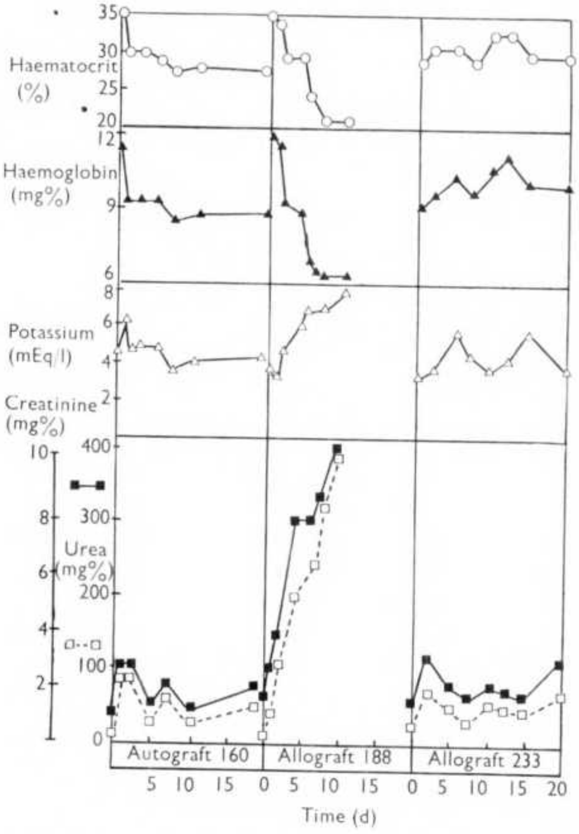

Fig. 1. The typical biochemical and haematological changes following an autograft, an allograft with severe rejection (pig no. 188) and an allograft with mild rejection (pig no. 233) are shown in representative graphs.

et al., 1973). In the cross-bred pigs obtained from different farms in group B 18 per cent survived for more than 14 days, 2 per cent for more than 20 days and none for more than 40 days, while in group C, where transplants were performed in different pure-bred pigs to ensure genetic disparity, the survival was longer, viz. 25 per cent for 14 days, 12 per cent for more than 20 days and 6 per cent for more than 40 days. This latter unexpected finding was at least partly due to death from complicating bleeding gastric ulcers in group B (*vide infra*). In this present large series of transplanted pigs the protracted survival seen in our previous series was not achieved (50 per cent longer than 14 days, 40 per cent over 20 days and 25 per cent over 40 days).

Biochemistry

Representative biochemical patterns from an autograft, a severely rejecting transplant and a minimally rejecting transplant are shown in *Fig.* 1. In the autograft animals a mild early elevation of serum urea and creatinine occurred, probably as a result of ischaemic damage. This elevation returned to normal within 10 days. No marked late fall in haemoglobin was noted. In animals undergoing severe rejection a sharp rise occurred in serum urea, potassium and creatinine within 2–3 days of transplantation. This rise persisted and the animals appeared able to tolerate very high levels for several days. Urine output was not measured. A marked fall occurred in haemoglobin and packed cell volume, but no significant changes were seen in leucocyte or platelet counts. In the animals surviving longer with little evidence of rejection, minimal elevation occurred in serum urea, creatinine and potassium and no significant change occurred in haemoglobin or haematocrit.

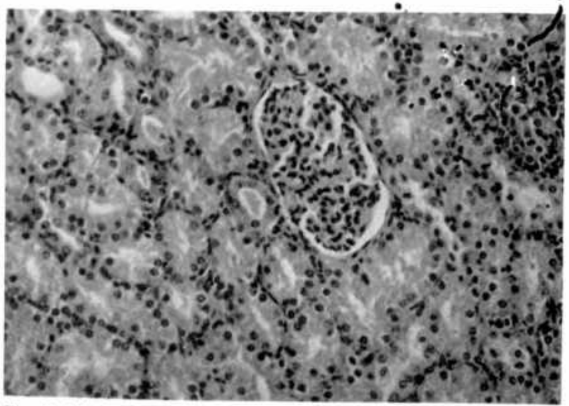

Fig. 2. Minimal evidence of rejection (histological category 1). This illustrates minimal rejection in which only slight tubular degeneration and scanty focal infiltration of mononuclear cells are evident. HE. (× 106.)

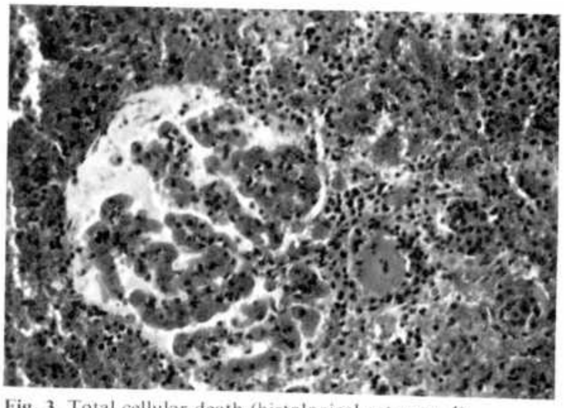

Fig. 3. Total cellular death (histological category 4). Complete haemorrhagic infarction involving all renal elements, accompanied by moderate interstitial infiltrate of mononuclear and polymorphonuclear leucocytes. HE. (× 106.)

Histology

The histological material was reviewed independently by the three authors and grouped according to evidence of cellular rejection. The findings could be grouped into four patterns (*Figs.* 2, 3). The patterns and mean survival times are shown in *Table III*. In group B no difference in survival was noted, despite variable patterns of rejection. In fact, only in the 20 per cent of animals in group C showing minimal rejection was survival prolonged to a mean of 24·6 days. In the 18 animals in which a biopsy was performed the features noted were similar to the subsequent pattern at autopsy. No resolution was noted, but unfortunately

Gastric ulcer	2	16	3	0
Others including haemorrhage after biopsy, peritonitis, renal vein thrombosis and long P.M. interval	2	3	0	2

in all the biopsy cases no more than 5 days elapsed between biopsy and autopsy. No firm conclusion can therefore be drawn about possible spontaneous reversal of rejection as has been seen in liver allografts in unimmunosuppressed pigs (Dent et al., 1971a; Terblanche et al., 1973). The four histological patterns shown in *Table III* are described below.

1. *Minimal evidence of rejection* (*Fig.* 2): The kidneys showed minimal changes of cellular rejection. This manifested as an almost complete absence of interstitial cellular response, or as inconspicuous focal interstitial mononuclear cell infiltrates of both the cortex and medulla which tended to occur perivascularly. Vascular and glomerular changes were generally absent. In a few pigs the mononuclear infiltrate was more severe, and in these the vascular endothelial cells were prominent and the glomeruli showed segmental cellularity largely due to epithelial and mesangial cell proliferation. The tubules were remarkably normal except for hydropic degeneration which was unrelated to the severity of the interstitial infiltrate or the glomerular or vascular changes. In 2 kidneys there were changes of acute pyelonephritis.

2. *Significant rejection*: A constant feature in these kidneys was a more pronounced patchy interstitial infiltrate of mononuclear cells. In many the infiltrates became confluent and presented as sheets of pyroninophilic mononuclear cells in an oedematous interstitium. The infiltrate also included plasmacytoid cells. The tubules showed changes varying from severe degeneration to necrosis, but tubular regeneration indicative of post-necrosis was also apparent. Once again hydropic degeneration was a notable feature. Even the severely damaged epithelium appeared hydropic, suggesting that this change had existed before the onset of necrosis. In many of the tubular lumina, aggregates of polymorphonuclear cells occurred. In a few cases there were areas of patchy interstitial capillary haemorrhage, focal and segmental glomerular necrosis or atrophy (suggestive of earlier necrosis) and vascular lesions consisting of endothelial cell swelling, mononuclear cell infiltration of the media and, rarely, fibrinoid necrosis. Occasionally the glomerular tufts showed generalized increased cellularity.

3. *Cortical necrosis with rejection*: These biopsies were characterized by patchy areas of haemorrhagic infarct-like necrosis of both cortex and medulla, which alternated with areas of viable parenchyma showing pronounced cellular infiltrates, as well as notable tubular, glomerular and vascular changes. In the areas of necrosis all tissue elements showed necrosis of varying duration associated with prominent interstitial haemorrhage. In these areas there was evidence of an interstitial infiltrate which included many polymorphonuclear as well as the usual mononuclear cells. Often all cellular elements had disintegrated and only poorly stained cell outlines were evident, which were mingled with chromatin debris. The polymorphonuclear cells were more obvious at the borders of the necrotic areas. The viable areas always occurred at the junction of the cortex and medulla and included variable amounts of both these tissue components. The changes observed in the non-necrotic areas were similar but more severe than those described in the preceding group. Necrosis of the large arterial radicles was prominent and these frequently contained thrombi.

4. *Total cellular death* (*Fig.* 3): Complete haemorrhagic infarction of the entire kidney was noted in these biopsies. In some this had occurred recently, while in others even the cell outlines of the necrotic tissues were no longer distinguishable and the necrosis was of longer duration. In every respect the appearances were similar to those described in the necrotic areas of the kidneys in the third category, and differed only in that the necrosis was total instead of subtotal.

Complications

The major complications which caused death in these animals are shown in *Table IV*. In the autografts the principal causes of death were pneumonia, ureteric leak and gastric ulceration. In the animals of groups

B and C rejection was often present in addition to the apparent cause of death. However, this rejection was mild and frequently considered insufficient to be the sole cause of death (histological categories 1 and 2). The principal complication in group B (i) was fatal gastric ulceration, constituting 35 per cent. These ulcers were large, as previously noted after liver transplantation (Dent et al., 1971b), and death resulted from haemorrhage or occasionally perforation. In 48 per cent of cases no cause of death other than rejection could be found, even though this was often only mild or moderate (histological categories 1 and 2). It is of interest that in animals in group B (ii) gastro-enterostomy did not prevent ulceration completely and one-third still apparently died from this complication. In group C using the same procedure no ulcers occurred, and the major cause of death was rejection, although once again this was often mild. In 20 per cent there was severe pneumonia.

Discussion

In previous studies of kidney transplantation in the pig few experiments without immunosuppressive manœuvres have been described, and also few data of biochemical and histological changes under these circumstances are available. The unique response of the pig to liver transplantation with minimal rejection (Calne et al., 1969; Dent et al., 1971a) makes such a study essential. The present detailed study was designed to investigate the response of the unimmunosuppressed pig to kidney allografts. The survival and biochemical and histological features were specifically studied and compared with our previously reported small series in which prolonged survival had been noted (Terblanche et al., 1973).

In the group of 71 allografts surviving for longer than 5 days a wide range of survival times was noted. The differences in survival could not be correlated with ischaemic intervals. There was some decrease in mortality in the latter part of the series when gastro-enterostomy was performed to prevent gastric ulceration, which was a complication in many of the animals. Haemorrhage from these ulcers and pneumonia contributed significantly to the shortened survival times in the present series. This is particularly important as in 55 per cent of group B (transplantation between cross-bred pigs) and 60 per cent of group C pigs (transplantation between different pure-bred pigs) histological features of rejection did not appear severe enough to have caused death (histological categories 1 and 2).

Biochemical investigation of autografts showed a minimal rise in urea and creatinine levels for 4 days after transplantation, probably related to the operative procedure. In allograft animals undergoing marked rejection this rise continued rapidly and persisted until death. It was accompanied by a fall in haemoglobin and haematocrit irrespective of whether gastric ulceration was present. Hence, at least some of the haematological changes were attributable to rejection, although no significant changes were noted in total leucocyte or platelet counts. In animals without biochemical evidence of rejection no similar changes were noted in haemoglobin or haematocrit, and histology showed mild to moderate rejection.

The histological patterns fell into four categories. None showed the severe cellular infiltrate noted in unimmunosuppressed dog kidney allografts (Porter, 1964). In the autograft animals death was caused by gastric ulceration, pneumonia and ureteric leaks, and no features of infection, or features similar to those of rejection, were seen. This is unlike the liver autografts previously reported from our laboratory, where infection (ascending cholangitis) confused the histological picture (Dent et al., 1971a). The 55 per cent of animals in group B and 60 per cent in group C which showed rejection, apparently insufficient to cause death, also showed only moderate biochemical changes. In these animals death was attributed to pneumonia or gastric haemorrhage or other undetermined causes.

Hence, the response of the unimmunosuppressed pig to kidney allotransplants is not as violent as that reported in the dog (Porter, 1964), and 10 per cent of animals survive beyond 20 days and some as long as 1 year, with evidence of chronic low grade rejection at autopsy.

The major histocompatibility locus for pigs has recently been demonstrated by mixed lymphocyte culture and lymphocytotoxicity allo-antisera (Vaiman et al., 1970; White et al., 1973), and the survival of renal allografts has been shown to be related to serological identity. In another more recent study in our laboratory no serological identity was detected in pigs of different breeds (Parker et al., 1975), yet in group C allografts between different pure-bred pigs 12 per cent survived beyond 20 days. In our previously reported series the mean survival time for different breed transplants was more than 20 days. Furthermore, in our laboratory 85 per cent of liver allografts in unimmunosuppressed cross-bred non-litter mates showed prolonged survival of up to 2 years, and in some, resolution of histological rejection has been noted (Terblanche et al., 1973).

The present results indicate that the cellular immune response of the pig to renal transplantation is variable, even without the addition of immunosuppressive agents as used by others (Perper et al., 1971; Symes et al., 1972), and further intensive studies are required of the anomalous response of this animal to a vascularized organ graft. It is concluded that the wide range of rejection response and the variable sporadic long term survival obtained in the pig kidney allograft model make it unsuitable for investigation of immunosuppressive régimes.

Acknowledgements

The continued interest and support of Professor J. H. Louw, Head of the Division of Surgery, University of Cape Town, are gratefully acknowledged. Experiments were conducted with the assistance of the staff of the J. S. Marais Surgical Laboratory; biochemical determinations were made by Mesdames J. Green, J. Fourie, C. Rose Innes and P. van Heerden, and histological specimens were prepared by Mrs S. Carstens and Mr S. E. Abbott.

Financial assistance was received from the Medical Research Council of South Africa, the CPA, the Staff Research Fund of the University of Cape Town and the Chris Barnard Fund.

Injuries caused by rubber bullets: a report on 90 patients

R. MILLAR, W. H. RUTHERFORD, S. JOHNSTON AND V. J. MALHOTRA*

SUMMARY

The injuries in 90 patients caused by rubber bullets are described. There was 1 death and 17 people in the series had permanent disabilities or deformities. In 41 patients the injuries necessitated admission to hospital. One fatality outside this series is known. Injuries to the head and neck were frequent and severe.

IN July 1970 in Northern Ireland the British Army introduced a new missile, the rubber bullet. This article describes the injuries to 90 patients caused by this missile. Cases were collected by contacting all the hospitals in Belfast and Londonderry and asking for details about rubber bullet injuries. Most of the serious and many of the minor injuries were seen personally by one or more of the authors.

Ballistic details

The rubber bullet is a blunt missile which is intended to administer a painful slap severe enough to deter stone throwers but not severe enough to cause major injuries. It is the mechanical descendant of the wooden club or baton. The first attempt to modify a baton so that it could be fired was in Hong Kong. This missile was made of wood, and the Army spoke of 'firing baton rounds'. For the civil disturbances in Northern Ireland the wooden missile was replaced by one made of hard rubber. The Army has continued to speak of 'firing baton rounds', but civilians have always referred to the missiles as 'rubber bullets'.

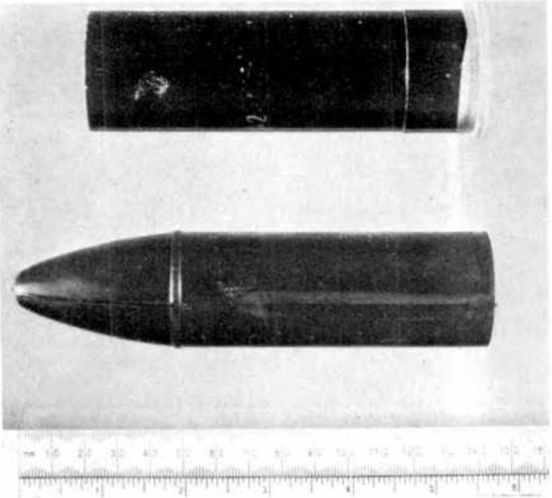

Fig. 1. Rubber bullet with its cannister.

When the rubber bullet was designed it was decided to use it for firing in a weapon already in production. The weapon chosen was designed originally for firing canisters of CS gas, and is in current use by the Royal Ulster Constabulary for this purpose. The army refers to this weapon as the 'RUC riot gun'. A rubber bullet can also be fired from the Verey pistol.

The term 'bullet' gives a correct impression of shape, but not of size—it is 15 cm long, 3·5 cm in diameter and weighs 135–140 g. It is mounted in a canister with a charge of 55 grains in the base (*Fig.* 1). It fits loosely into the barrel of the riot gun and is highly unstable in flight. The muzzle velocity is 73 m/sec, but with tumbling movement and high wind resistance it loses energy very rapidly. The loose barrel and tumbling flight are also responsible for its inaccuracy. At 18 m it is difficult to hit a target 2 m in diameter.

Patients

Table I shows the sex distribution. It is noteworthy that while women formed 33 per cent of the total series, they represented only 10 per cent of the patients who required admission to hospital. Of the less serious cases where admission was not necessary, just over 50 per cent were women.

Table II shows the age distribution. The youngest patient was 7 years old and the oldest 67.

Table III shows the anatomical site of the injuries. In 5 cases two areas of the body were injured, giving 95 sites in 90 patients. The great majority of these lesions were on the anterior aspect, a few were lateral and only two were on the posterior aspect, one on the back of the neck and the other on the back of a leg.

Injuries to specific organs

1. *Skin and soft tissues*

Of the 90 patients, the records note the absence of obvious damage to the skin and soft tissues in only 2 or 3 cases. By far the most common lesion was a bruise, and this was usually elongated, in some cases giving a striking reproduction of the shape of the bullet (*Figs.* 2, 3, 4). In 2 cases it was noted that the bruise was circular, presumably from an end-on impact. The typical shape of the bruise was somewhat less evident in face and head injuries. Injuries to the face characteristically caused gross swelling and bruising of the cheek, lips and eyelids, with or without abrasions and lacerations (*Figs.* 5, 6). There was one scalp laceration with no skull fracture, but in one case of very severe comminuted skull fracture there was no overlying laceration.

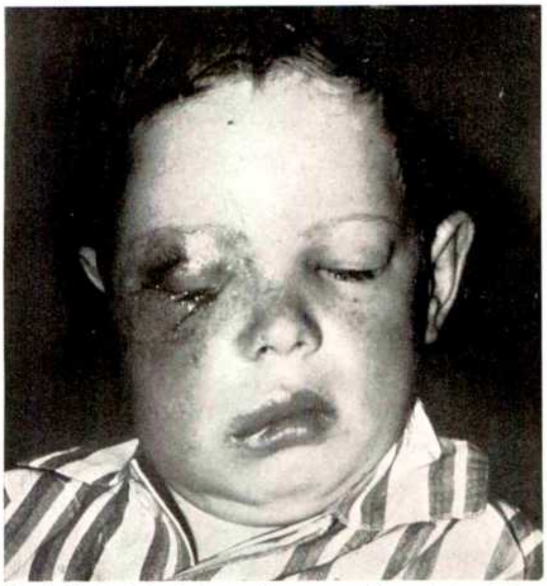

Fig. 5. Typical face injury with gross swelling of the orbit and undisplaced malar fracture.

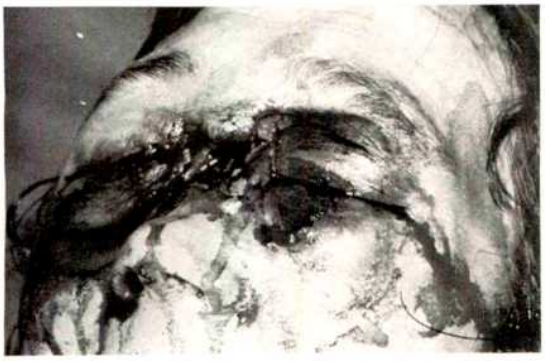

Fig. 6. Severe injury with compound fracture of the nose, maxillary fracture and destruction of both eyes.

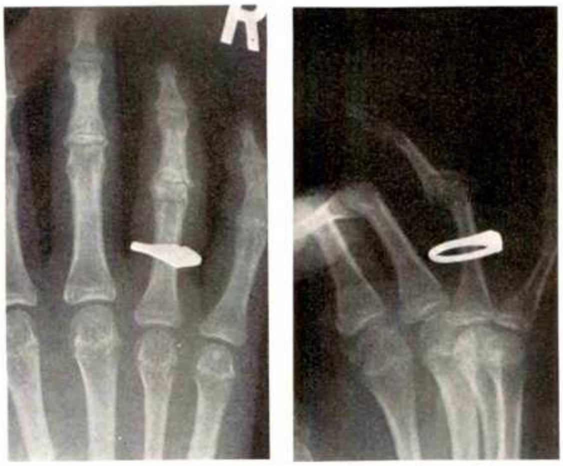

Fig. 7. Fracture of the base of the middle phalanx of the right ring finger.

common injury was a fracture of the malar and/or nasal bones. Blow-out fracture of the orbit also occurred. In one case the force was sufficient to displace the maxilla laterally and in another the mandible was fractured and displaced. One patient had a depressed fracture in the frontotemporal region combined with massive shattering of the whole vault of the skull (*Fig*. 8). Fractures due to frontal impact were less common. In several cases the nasal bones were comminuted and flattened. In one of these there was an associated fracture of the frontal bones with a cerebrospinal fluid leak for several days. In another the whole maxilla was driven downwards and backwards and there were associated fractures of the malar bones and nose and a blow-out fracture of the left orbit (*Figs*. 6, 9). In this patient both eyes were ruptured. Another patient, who suffers from osteogenesis imperfecta, had a direct impact on the frontal bones, resulting in a depressed fracture and an extradural haematoma which required surgical intervention.

3. *Eyes and ocular adnexa*

Twenty-four cases had injuries to the eyes or adnexa, 4 of which were bilateral; 10 right eyes and 18 left were involved (*Table V*). Two (8 per cent) of the patients were women. This is similar to the percentage of women among inpatients (10 per cent) rather than in the total series (33 per cent). In comparison with injuries to other sites of the body there was a similar age range but more cases occurred in the older age groups. All except 4 were treated as inpatients, with an average duration of 10 days' hospitalization.

Gross ecchymosis, periorbital and orbital oedema were a feature of all the cases (*Fig*. 5). In 7 cases bruising and lacerations of the lids alone were involved and these all had good visual results and no permanent disability. Thirteen cases had associated facial or skull fractures of which 6 required surgical reduction.

Twenty globes were injured, contusion accounting for 12. Severe visual loss was caused by traumatic cataract in 2 and by choroidal tears and retinal scarring in the macular region in 6. There were 8 ruptured globes all of which resulted in blindness; 4 had to be excised. A bilateral case who was severely injured at short range is shown in *Fig*. 6. Apart from visual loss, permanent disability was caused by anosmia in 3 cases and a marked change of facial appearance in 3 cases.

4. *Brain*

In 7 patients there was loss of consciousness. In 2 this was very brief—a matter of a few minutes—and in another 2 there was amnesia for less than 1 hour. Of these 4 mild cases, one was associated with a fractured mandible and the other 3 had no bony injuries. The 3 more severe cases of brain injury were associated with skull fractures. One of these made a complete recovery with no disability, one recovered well in spite of the damage to a frontal lobe noted at operation and the third patient died (*Fig*. 8). At operation he was noted to have gross cerebral oedema. It is noteworthy that no unconsciousness or amnesia was noted in any of the

Skull	3	0	3
Total	20	15	35

In one case a bruise on the calf of the leg later broke down with considerable sloughing of the subcutaneous tissues. This was skin-grafted and healed well. One bruise over the lower chest wall and epigastrium increased in size and on the fifth day measured 30 cm and was fluctuant; 150 ml of thin, bloodstained fluid, full of fat globules, were removed, presumably the result of traumatic fat necrosis.

2. *Bony injuries*

The only fracture in a long bone of the limbs was in a finger (a dislocation of a proximal interphalangeal joint with fracture of the base of the middle phalanx) (*Fig.* 7). In this case the finger was pinched between the rubber bullet and a wall. In the trunk the only fractures were of the ribs. Of 24 chest injuries, 9 of which required admission, rib fractures occurred in only 2 cases.

By contrast, fractures of the face and skull were relatively common. There were no fractures among 18 injuries to the head where admission was judged unnecessary. Of 33 patients with head injuries who were admitted, 21 patients had sustained fractures of the face and skull bones. Several patients had fractures at more than one site, making a total of 35 fractures. *Table IV* sets out the details of these fractures.

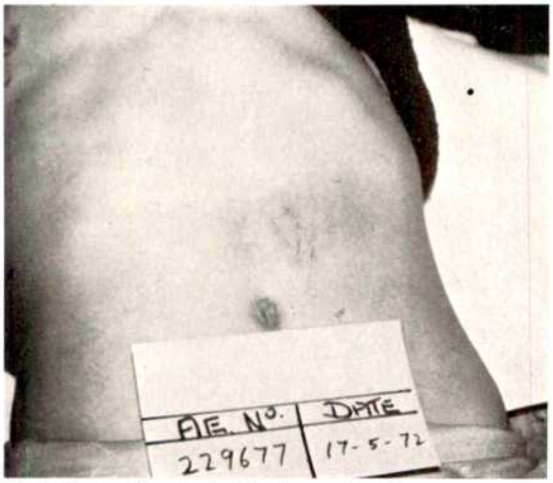

Fig. 2. Typical longitudinal bruise on the abdomen.

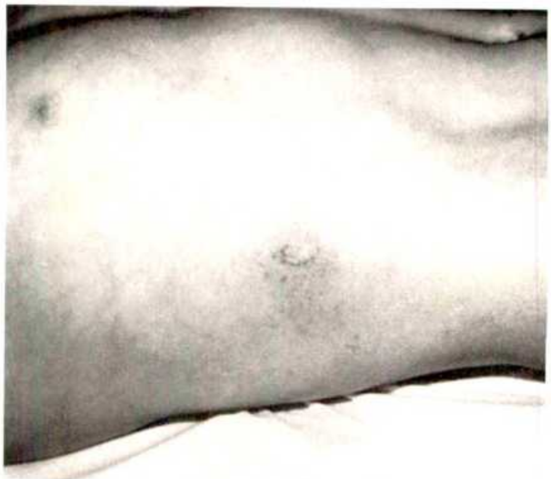

Fig. 3. Circular bruise over right lower ribs.

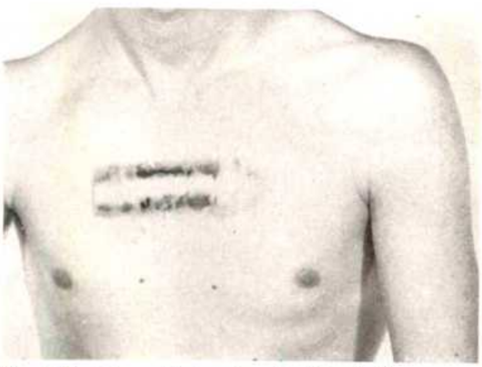

Fig. 4. Bruising with imprint of rubber bullet.

Fractures of the facial bones and skull did not show any unusual features as compared with those due to other types of blunt trauma. The fracture patterns reflect the direction and momentum of the missiles and the inherent lines of weakness in the skeleton of the face. In most cases the impact was from the side and a

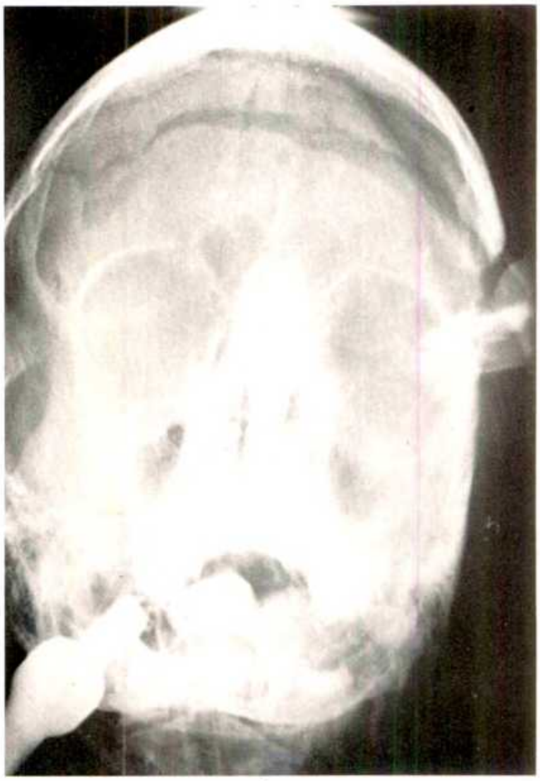
No cases fell into the 'fair' category (6/18–6/36).

cases with eye injuries, and that only one facial bone fracture was associated with amnesia.

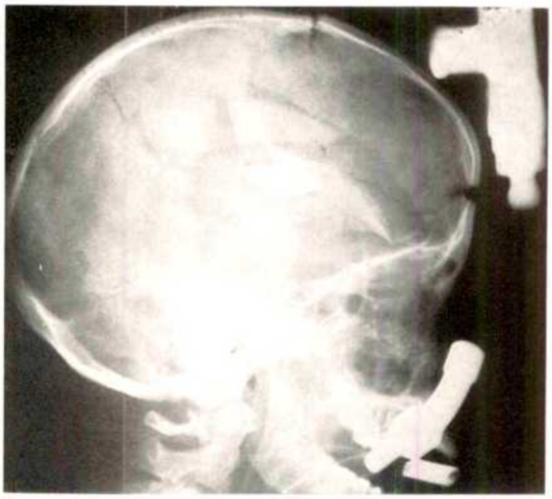
5. *Lungs*

Of the 9 cases of injuries to the chest which were admitted to hospital, 7 had injuries of the lung (the other 2 had subdiaphragmatic injuries). Three of these have been reported elsewhere (Shaw, 1972). None of the chest injuries treated as outpatients had lung damage visible on X-ray.

The clinical picture in the lung injury cases was striking. Within minutes, if not seconds, of injury the patient coughed up blood. In some cases the notes state that it was not frank blood but very frothy sputum which was either streaked with blood or completely red. In every case so presenting, X-rays taken in the casualty department revealed an opacity in the lung (*Fig.* 10). The patients were distressed and dyspnoeic but not cyanosed. Some caused sufficient anxiety to be sent to the intensive care unit for a short period. Within a few days there was striking improvement in the clinical condition. Follow-up has been difficult but some opacities have remained for 4 weeks. In 1 case a small pneumothorax accompanied the lung contusion and in 2 cases there were fractured ribs. In the 3 cases in which the $P\text{o}_2$ was recorded it varied between 45 and 76 per cent (breathing air).



b



c

Fig. 8. *a*, Circular bruise lateral to the left eye. Anteroposterior (*b*) and lateral (*c*) X-rays of the skull.

6. *Liver*

There was 1 case of injury to the liver. This 13-year-old boy was admitted with a circular bruise over the right lower chest wall (*Fig.* 3). There was tenderness and guarding in the right upper quadrant, and it was

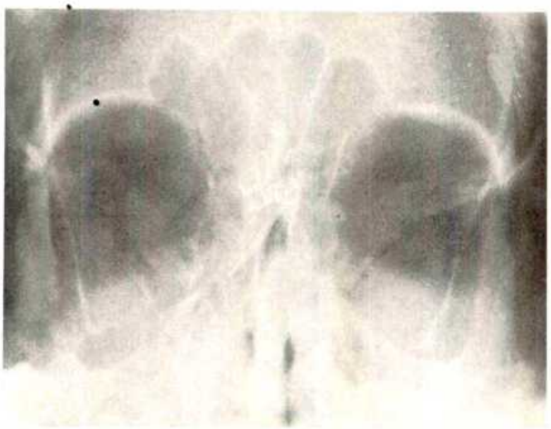


Fig. 9. Postoperative X-ray showing fractures of the nose, maxilla, orbital floor and malar bone of the patient shown in *Fig.* 6.

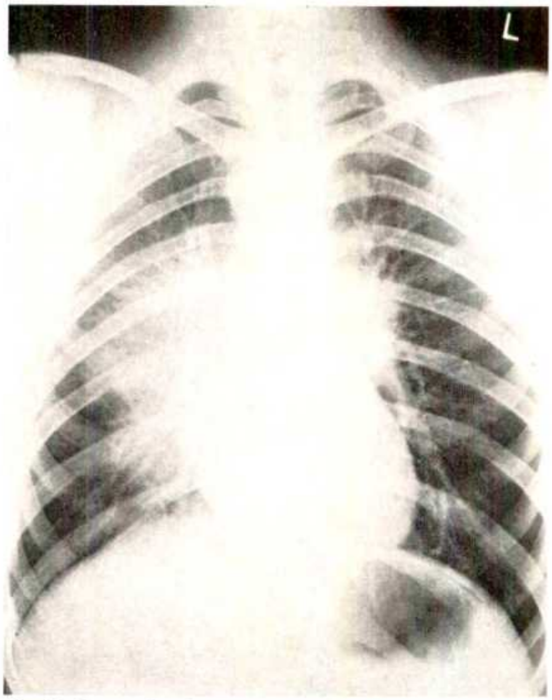

Fig. 10. X-ray showing contusion of the lungs of the patient shown in *Fig.* 4.

thought possible that he might have blood in the peritoneum. However, it was decided to treat him conservatively. Two days after admission he developed jaundice which was 4·0 mg per cent at maximum. The serum glutamic oxalo-acetic transaminase, lactic dehydrogenase and alkaline phosphatase were all markedly elevated. An intravenous cholangiogram was normal. The condition resolved spontaneously and he was discharged in good health on the twelfth day after injury.

7. *Spleen*

In 1 case, a 16-year-old boy, the spleen was ruptured. On initial examination the only positive finding was slight tenderness in the lower left costal area. X-ray revealed no fracture of the ribs. Two hours later he developed pain and tenderness in the abdomen and general signs of blood loss. At operation there was a tear on the diaphragmatic surface of the spleen. Splenectomy was followed by an uncomplicated recovery.

8. *Intestine*

The single case recorded was a 67-year-old man who was struck on the abdomen. On examination there was a circular bruise in the left iliac fossa and marked tenderness, guarding and rebound tenderness. At laparotomy there was a perforation of the jejunum. Bruising was noted around the perforation and at multiple sites in the jejunum. The perforation was sutured and the patient made an uneventful recovery.

Range of bullets

Details about range are only available in 19 cases. These are set out in *Table VI.*

Final state

Table VII sets out the final state of the 90 patients. As some of the injuries have been sustained very recently this is a table of the disabilities and disfigurements as they seem likely, but in most cases there is little doubt as to whether complete recovery can be expected or not. The 3 cases of anosmia and 2 of the 4 with facial disfigurement are also listed under their eye disabilities, so that the 22 types of disability and disfigurement occurred in 17 patients. One of the patients with disfigurement is illustrated in *Fig.* 11.

Discussion

The purpose of this article is to give a description of the type of injuries caused by rubber bullets. While we have reported on every case attending the Royal Victoria Hospital, the Royal Belfast Hospital for Sick Children and the Altnagelvin Hospital, Derry, in the period under study, these cases are not necessarily typical of all the injuries that occurred, as emotional and other factors play a part in determining whether hospital attendance takes place or not. Some will avoid attending hospital for fear of being judged guilty of rioting. Others will attend for propaganda or litigation purposes, when they believe that it may help them to establish that they have been wrongfully assaulted. However, with serious injuries it is probably rare for patients not to attend hospital. This means that the sex distribution of hospitalized patients is probably fairly representative of all those injured, while the distribution of those attending as outpatients only, reflects more their motivation than the type and severity of the injury. Women formed 10 per cent of inpatients, 33 per cent of the total series and 51 per cent of outpatients. The injuries of the 49 outpatients should, therefore, be regarded merely as examples of a few of the minor injuries which were sustained. On the other hand, the injuries of the 41 inpatients can be looked upon as being a fairly complete list of all the severe injuries which have occurred. The age distribution shows that 64 per cent of patients were in the second decade, and most of these were between the age of 1[illegible] and 14. For inpatients and outpatients the range is similar and severe injuries occurred in all groups. The predominence of young boys is therefore most likely due to the age distribution of the population at risk on the streets, and not due to the susceptibility of their tissues to injury.

As the missile is so erratic in its flight, one would expect random injuries all over the body in proportion to the surface area of each region. The surface area of the head and neck is 9 per cent, and of the lower limbs is 36 per cent. Statistically this means that the 51 head injuries in the series should have been matched by 204 leg injuries (in our series there were only 11), and that the 33 head injury patients who were admitted should have been coupled with 132 leg injuries. In fact, no patient was admitted with a leg injury. It is obvious that the tissues of the eyes, face and skull bones and brain are particularly susceptible to a blow from a missile of this size, weight and speed. The abdomen is not nearly so susceptible as the chest. Head injuries are particularly serious as brain damage may be fatal, and a very high percentage of injuries to the eye results in blindness. While damage to thoracic and abdominal organs is comparatively rare, it would appear that injuries are possible to all the viscera.

The question of range is difficult to assess. We have been dependent on estimates by the patients or their relatives and friends. Judging distances at any time is not easy and in a highly charged emotional atmosphere one has to treat all information with a certain scepticism. However, many of these estimates were obtained within minutes of the injury and in some cases careful measurements were taken by friends. In two street situations it was possible, by examining the location of the incident, to confirm the patient's judgement.

Allowing for inaccuracies in particular estimates, it is nonetheless probable that the general picture given is not far from the truth. It is striking that the range for inpatients is no shorter than that for outpatients. In the case of the boy killed the alleged range was 2–3 m. The range was 8 m in the patient with extreme facial injury and loss of both eyes. In the point blank injury only a massive bruise resulted. Other short ranges only resulted in minor injuries while some of the severe injuries had ranges of 17–25 m. This highly irregular pattern is partly due to the precise anatomical site which the bullet strikes and partly due to the flight path of the particular missile. Other factors may be important. Ricochets off the ground and walls are common with such a missile. Despite short ranges, these rapidly dissipate the energy produced and thus decrease the severity of the injury.

There was 1 death in our series and another that we heard about. In the one from our series three factors may have contributed to the fatal outcome—the short range, his age (11 years) and an end-on impact. The other case was a young man who sustained a chest injury from a rubber bullet in Strabane. He was taken to Lifford Hospital in the Republic of Ireland, but was dead on arrival. At the inquest doubt was expressed as to whether death was due directly to the chest injury or to respiratory obstruction during the journey to hospital.

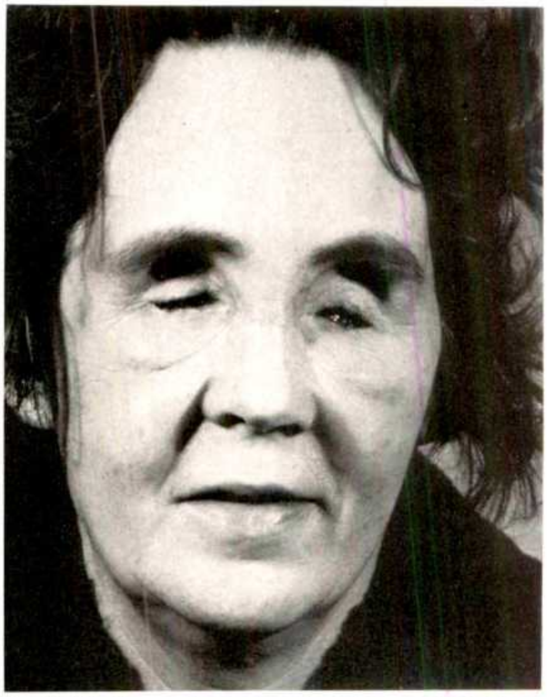

Fig. 11. Final cosmetic result in the patient shown in *Figs.* 6 and 9.

Table VI: RANGE OF BULLETS FROM FIRING TO IMPACT

Range (m)	Outpatients	Inpatients	Total
0–4	3	3	6
5–13	2	2	4
14–25	1	6	7
25	1	1	2
Total	7	12	19

Table VII: FINAL STATE

Dead	1
Blind in both eyes	2
Blind in one eye	7
Severe loss of vision in one eye	5
Disfigurement of face	4
Anosmia	3
Stiffness of finger joint	1
No permanent disability or disfigurement	62

The number of rounds fired during the period under study was approximately 33 000. With 1 death in our series and another elsewhere, this gives a mortality ratio of 1 : 16 000. Of the remaining 40 patients who required hospital admission, 17 were left with permanent disabilities or disfigurements. This gives a serious injury ratio of 1 : 800 and a disability ratio of 1 : 1900.

Despite the low mortality the rubber bullet cannot be considered completely safe in its present form. This is chiefly a consequence of its inaccuracy at the

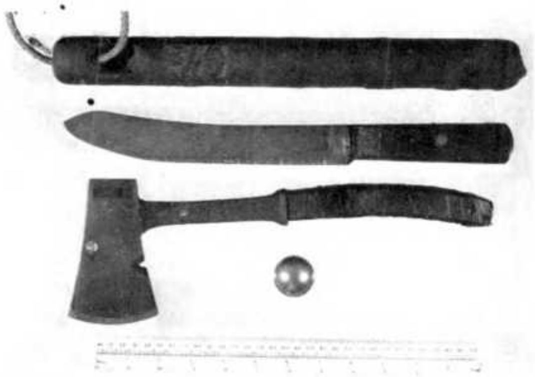

Fig. 12. Some missiles used in street riots.

recommended range of 30 or more metres. No serious injuries resulted from impacts in the lower limbs and only one from impacts on the abdomen. Impacts on the chest and head rather frequently produced serious injuries. However, not only is it impossible to avoid vulnerable areas of an individual, but the bullet may miss the target completely and strike another person. It would, therefore, be desirable to replace the present missile with one whose accuracy is considerably increased without a simultaneous increase in wounding potential. We are interested to hear that such a missile has recently been produced. It is a bullet made of solid plastic material and is said to be much more accurate.

The whole question of the use of rubber bullets cannot be fully understood without some reference to the context in which they are used. *Fig*. 12 shows some of the missiles which have been thrown in street riots in Belfast. If rubber bullets were withdrawn and the soldiers were armed only with rifles and machine guns it is certainly possible that the mortality and morbidity would have been much higher.

Acknowledgements

We are grateful to our colleagues in the hospitals of Belfast and Londonderry who supplied us with details of their cases. We thank the Medical Illustration Department of the Royal Victoria Hospital for their help, and patients and their relatives for giving permission for the use of photographs.

Incidental appendicectomy with laparotomy for trauma

LAWRENCE W. NORTON, MARNA SWEENEY AND BEN EISEMAN*

SUMMARY

Incidental appendicectomy was performed in 83 of 206 patients undergoing laparotomy for abdominal trauma. No organs were injured in 42 per cent of the appendicectomy patients and in 17 per cent of the non-appendicectomy patients, thus making comparison between the groups unreliable. While the incidence of intestinal perforation was 21 per cent in the appendicectomy patients, the rate of wound infection was only 7 per cent. One complication (pelvic abscess) was possibly attributable to incidental appendicectomy.

Since males below the age of 50 face a significant risk of future appendicitis and represent the majority of patients with abdominal trauma, it may be advisable to perform incidental appendicectomy with laparotomy for trauma in such patients. Specific indications for incidental appendicectomy during laparotomy for trauma are suggested.

REMOVAL of a normal appendix is an acceptable addition to many elective operations. The rationale is to eliminate the risk of future appendicitis without increasing the operative morbidity. Numerous reports indicate that incidental appendicectomy can accomplish these goals during routine hysterectomy (Beath et al., 1958), cholecystectomy (Lowery and Lenhardt, 1962) and herniorrhaphy (Brown et al., 1962).

Incidental appendicectomy during laparotomy for trauma is usually avoided, however, because of reluctance to prolong the operating time by adding unessential surgery or to risk contamination by transecting a faeces-containing organ. Since abdominal trauma often occurs in younger persons who carry a significant risk of developing appendicitis in later life, it is reasonable to consider the advisability of incidental appendicectomy at the time of laparotomy for trauma. The morbidity of such surgery has not been determined.

This is a selective preliminary study evaluating the risk of performing appendicectomy during laparotomy for trauma. It suggests that incidental appendicectomy adds little, if any, morbidity to such surgery.

Patients and methods

During the 12-month period from May 1969 to April 1970 a total of 218 patients underwent laparotomy for abdominal trauma at the Denver General Hospital. Twelve patients died during surgery or immediately thereafter and were not included in the study. The remaining 206 patients survived for 5 days or longer. Of these, 154 were males and 52 were females. Their ages ranged from 5 to 72 years with a mean age of 28 years.

The cause of injury was gunshot in 78 (38 per cent), blunt trauma in 76 (37 per cent) and stabbing in 52 (25 per cent) patients. All the patients were received in the Emergency Department within 3 hours of injury. The mean interval between injury and initial examination was 35 minutes.

Incidental appendicectomy was performed in 83 patients (37 per cent of all the patients) during the course of abdominal surgery. Operations were performed by a total of 18 different surgical residents under direct operating room supervision of a staff surgeon. Surgeons removed the appendix when the initial incision provided adequate exposure and when the patient's condition was judged to be stable. Only 2 patients were found to have a surgically absent appendix. They were included in the non-appendicectomy group. No attempt was made to randomize patient selection.

Appendicectomy technique was uniform despite the large number of surgeons. Routinely, the base of the appendix was transected between clamps, tied with absorbable suture material and inverted through a silk purse string suture. No drains or antibiotics were used specifically because of appendicectomy.

Patients with and without appendicectomy were analysed for age, sex, type and degree of injury, preoperative status, postoperative complications and survival. Follow-up ranged from 5 days to 2 years with a mean of 2 months.

Results

The average age of the 83 appendicectomy patients was 29 years compared with 27 years for the non-appendicectomy patients. Males constituted 84 per cent of the appendicectomy group and 75 per cent of the others.

Table I: MECHANISMS OF INJURY

	Appendicectomy		Non-appendicectomy	
Injury	No.	%	No.	%
Gunshot	33	40	44	36
Stab	23	27	30	24
Blunt	27	33	49	40

The mechanisms of injury are listed in *Table I*. About one-quarter of the injuries in each group were inflicted by stabbing. The incidence of blunt trauma was slightly higher in the non-appendicectomy (40 per cent) than in the appendicectomy (33 per cent) patients.

Table II: ORGAN INJURY

No. of organs injured	Appendicectomy		Non-appendicectomy	
	No.	%	No.	%
None	35	42	21	17
One	33	40	55	45
Two	9	11	37	30
Three	5	6	9	7
Four or more	1	1	1	1

Table III: MAJOR POSTOPERATIVE COMPLICATIONS

Complication	Appendicectomy	Non-appendicectomy
Sepsis	1	3
Pneumonitis	2	10
Pulmonary embolism	0	2
Stress ulcer	2	1

The interval between injury and surgery averaged slightly more than 2 hours for both groups. Twenty (23 per cent) non-appendicectomy patients were hypotensive with a systolic blood pressure of less than 80 mm Hg at some time prior to surgery. Only 6 (7 per cent) appendicectomy patients were similarly hypotensive.

The number of abdominal organs injured in each group is shown in *Table II*. Negative laparotomy with no significant organ injury was more common in appendicectomy (42 per cent) than in non-appendicectomy (17 per cent) patients. The incidence of injury to one, three and four or more organs was similar in the two groups although two organ injury was more common in the non-appendicectomy patients.

The small intestine was perforated in 14 per cent of the appendicectomy patients and in 16 per cent of the others. Large bowel perforation occurred in 7 and 8 per cent respectively. In no case was the appendix itself injured. The incidence of splenic injury was comparable but liver injury was proportionately more common in the non-appendicectomy patients.

Wound infection, defined as purulent wound drainage with or without micro-organisms, occurred in 6 (7 per cent) appendicectomy and 21 (17 per cent) non-appendicectomy patients. Gram-negative bacteria were recovered from 7 of the latter wounds and from only 1 of the former. Staphylococci were cultured from half of the infected wounds in both groups.

Postoperative complications other than wound infection included sepsis, pulmonary embolism, pneumonia and stress ulcer (*Table III*). The incidence of complications was considerably higher in non-appendicectomy (32 per cent) than in appendicectomy (14 per cent) patients. With one exception, no significant sepsis occurred in the patients with incidental appendicectomy.

The single complication possibly attributable to appendicectomy was in a 19-year-old male with rupture of the spleen secondary to blunt abdominal trauma. Ten days after splenectomy and appendicectomy a pelvic abscess was drained. No bacteria were cultured from the abscess pus. The site of the appendicectomy appeared to be healing normally.

No operative deaths occurred among the patients with appendicectomy. Eight (6·5 per [illegible] non-appendicectomy patients died 5–25 days af[illegible] surgery. Respiratory complications were responsi[illegible] half of these deaths.

Discussion

Incidental appendicectomy can be justified only if the risk of future appendicitis exceeds the risk of complications resulting from the appendicectomy. Several recent studies indicate that the risk of appendicitis is significant under the age of 50 (Ludbrook and Spears, 1965; Ashley, 1967; Hewitt et al., 1969). Hewitt et al. (1969) determined that in early childhood almost 1 person in 6 can expect to undergo primary appendicectomy for suspected appendicitis. After the age of 50 the risk is 1 in 40. The expectation of appendicitis in a person 28 years old (the mean age of our injured patients) is about 1 in 18.

Until the age of 50, males have a slightly greater expectation of undergoing primary appendicectomy than females. At the age of 28, for instance, the probability of a male developing appendicitis in the next year of life is about 15 per cent greater than that of a female. In both males and females the risk of death from appendicitis is about 1 in 800.

It appears that the younger male, who is most apt to undergo laparotomy for trauma, faces an appreciable risk of developing appendicitis at some time in the future, although his expectation of death from such disease is negligible.

Numerous authors have evaluated the risk of incidental appendicectomy with elective operations (Howie, 1968). Myers and Schreier (1960) found no greater incidence of postoperative morbidity among 483 obstetrical surgery patients with incidental appendicectomy than among 1201 similar patients without appendicectomy. This experience has been confirmed in obstetrical and gynaecological procedures by Beath et al. (1958). Incidental appendicectomy has been reported to be possible during vaginal surgery without increasing the incidence of complications (McGowan, 1968).

Eiseman et al. (1959) found that appendicectomy performed during right inguinal herniorrhaphy in 429 patients increased neither recurrence nor complication rates. Keeley and Schairer (1962) and Shumake (1971) have reported a similar experience.

Whether incidental appendicectomy is as innocuous during cholecystectomy is debated. Komorn and Kaufman (1963), reporting 62 cases, found a wound infection rate nearly three times higher than in non-appendicectomy cholecystectomy patients. Conversely, Lowery and Lenhardt (1962) and Bogart and Sebesta (1969) reported no increase in complications when the appendix is removed during cholecystectomy. Interestingly, Lowery and Lenhardt (1962) found that 28 per cent of incidentally removed appendices were abnormal histologically. This appears to be a unique experience unsubstantiated in our patients or in other series.

Obviously the two groups of patients reported here are not comparable. The degree of injury in the non-appendicectomy patients as a whole was greater as evidenced by a higher incidence of preoperative hypotension, postoperative complications and deaths. No serious visceral injury was found in 42 per cent of the appendicectomy patients and in only 17 per cent of the non-appendicectomy group. Thus, many of the appendicectomies were simply a byproduct of negative laparotomy. This intrinsic selection prevents accurate comparison of morbidity and mortality between appendicectomy and non-appendicectomy patients.

It is significant, however, that with perforation of the intestine in nearly one-quarter (21 per cent) of the appendicectomy patients, the rate of wound infection was only 7 per cent, a figure comparable to that after elective uncontaminated operations.

Only one possible complication of incidental appendicectomy was identified. It is unlikely that pelvic abscess in a patient with splenic rupture would have occurred without appendicectomy, although evidence of definite faecal contamination was absent.

This preliminary study suggests that incidental appendicectomy does not appreciably increase the morbidity of laparotomy for trauma. A randomized, prospective trial is required to confirm this impression. Current evidence also suggests that incidental appendicectomy with laparotomy for trauma may be particularly advisable in the male under 50 years of age.

The precise circumstances in which it is justified to perform appendicectomy during laparotomy for trauma remain to be defined. All justification obviously assumes that the satisfactory condition of the patient will not be compromised by the slight additional operative time and theoretical threat of contamination. At the time of laparotomy for trauma incidental appendicectomy should be considered with progressively less enthusiasm under the following conditions:

1. *Negative exploration*: If laparotomy shows no visceral injury, appendicectomy is advisable and should entail no greater risk than with an elective operation.
2. *Perforating wounds of the small or large bowel*: When the peritoneal cavity is already grossly soiled with intestinal contents, appendicectomy cannot appreciably add to the hazard of infection.
3. *Perforating wounds of the stomach*: Since gastric contents are usually sterile and perforating wounds of the stomach heal well, the addition of incidental appendicectomy to repair of minor gastric perforations seems reasonable. It is analogous to adding appendicectomy to elective gastric surgery for ulcer disease.
4. *Splenic injury*: Splenectomy for injury characteristically involves little risk of sepsis. Adding appendicectomy to splenectomy should be nearly the equivalent of performing appendicectomy at a negative laparotomy, assuming that all the blood is evacuated from the peritoneal cavity.
5. *Major vascular repair*: If there are no other damaged organs and injury to a major vessel such as the abdominal aorta or vena cava can be repaired by suture alone, appendicectomy should not add a significant risk. It should not be employed where a prosthesis is required.
6. *Hepatic and pancreatic injury*: Bile, blood, pancreatic juice and bacteria comprise such a dangerous pabulum that only with the most minor damage to the liver and pancreas should incidental appendicectomy be performed.

Even these relative indications for appendicectomy must be ignored if the patient's general condition is unstable or the appendix cannot be visualized in its entirety without extensive dissection.

A prospective study of acute pancreatitis

C. W. IMRIE AND A. S. WHYTE*

SUMMARY

All 78 patients with acute pancreatitis admitted to one hospital in a 2-year period were included in a prospective survey of conservative management. The overall mortality rate was 11·5 per cent, being 46 per cent for 11 patients subjected to early laparotomy and only 6 per cent for patients managed without operation. Twenty-six patients were considered to have severe acute pancreatitis and all 9 deaths occurred in this group.

Biliary disease was present in 51 per cent of patients, and the majority of those with biliary disease were over 60 years old. Alcohol-related acute pancreatitis occurred in 26 per cent of the total patients, and none of this group was over 60 years old. Acute pancreatitis was considered idiopathic in origin in only 13 per cent of the patients.

Elective biliary surgery in 30 patients has resulted in freedom from recurrent attacks of acute pancreatitis for the follow-up period (12–30 months).

The results compare favourably with those in which glucagon and high dosage aprotinin (Trasylol) have been utilized in the management of acute pancreatitis.

THE mortality rate for acute pancreatitis in the United Kingdom has been reported as 20–25 per cent (Pollock, 1959; Trapnell, 1966). Recent studies have indicated that certain specific therapeutic agents may be of value in the management of acute pancreatitis. Thus, intravenous glucagon was utilized in an uncontrolled study of the management of 30 patients (Condon et al., 1973). There were only 2 deaths in this group and it was proposed that glucagon may be of value in reducing the mortality rate. By contrast, a controlled double blind trial of high dosage aprotinin (Trasylol) revealed a difference between a control group of 52 patients, in which the mortality rate was 25 per cent, and the Trasylol-treated group of 53 patients with a mortality rate of 7·5 per cent (Trapnell et al., 1974).

The present article reports the results of the initial 2 years of a prospective survey of acute pancreatitis. A well-supervised conservative management regimen was utilized and neither glucagon nor Trasylol was administered.

Patients

All 78 patients with acute pancreatitis admitted to Glasgow Royal Infirmary in 1971 and 1972 were included in the study. The surviving patients have been followed up on a regular basis as outpatients and 94 per cent have been seen at least 1 year after their initial attack. Clinical examination, haematological and biochemical estimations including liver function tests and estimations of fasting cholesterol and triglyceride levels together with biliary radiology were performed in all the cases.

Diagnostic criteria

The diagnosis was based on the clinical presentation, hospital course of the illness and biochemical findings in 67 patients, while the diagnosis was not suspected and thus made at laparotomy in 11 patients. Over 90 per cent of the patients presented with upper abdominal pain, and only 2 of the 78 cases had no vomiting recorded. Only 6 patients had previously suffered an attack of acute pancreatitis. Serum amylase elevations greater than 1200 i.u./litre were accepted as confirming the initial diagnosis.

The majority of patients had timed urine collections performed which allowed calculation of amylase clearance and creatinine clearance. The normal range of amylase clearance is 2·7–3·1 ml/min and in acute pancreatitis usually exceeds 4 ml/min (Levitt et al., 1969). A high amylase clearance was useful in confirming the diagnosis in 13 patients presenting later than 24–48 hours after the onset of symptoms, and defined a single case of macro-amylasaemia with characteristic low amylase clearance (Imrie et al., 1973).

The criteria for accepting biliary disease as an aetiological factor were operative and histological. Radiological evidence was accepted on its own in 5 patients only, who were unwilling or unfit for surgery.

On admission to hospital all the patients were specifically questioned and an assessment made of alcohol intake. Patients accepted as having a regular heavy intake of alcohol consumed on a daily basis at least 350–700 ml of whisky or 3 litres of beer or 500 ml of wine.

Acute renal failure was accepted when a rise in blood urea over 100 mg/100 ml failed to respond to adequate fluid replacement.

Assessment of severity

It is difficult to assess accurately the severity of an attack during the early period of admission to hospital. Initial severe hypotension and hypovolaemia often respond rapidly to fluid replacement. Many of the best indices of severity are only apparent after a longer stay in hospital. The severity of the attack was assessed in retrospect based on the following criteria: (1) hypocalcaemia (< 8·0 mg/100 ml), (2) acute renal failure and (3) pseudocyst or abscess formation (Trapnell 1966, 1971).

---

* Glasgow Royal Infirmary.

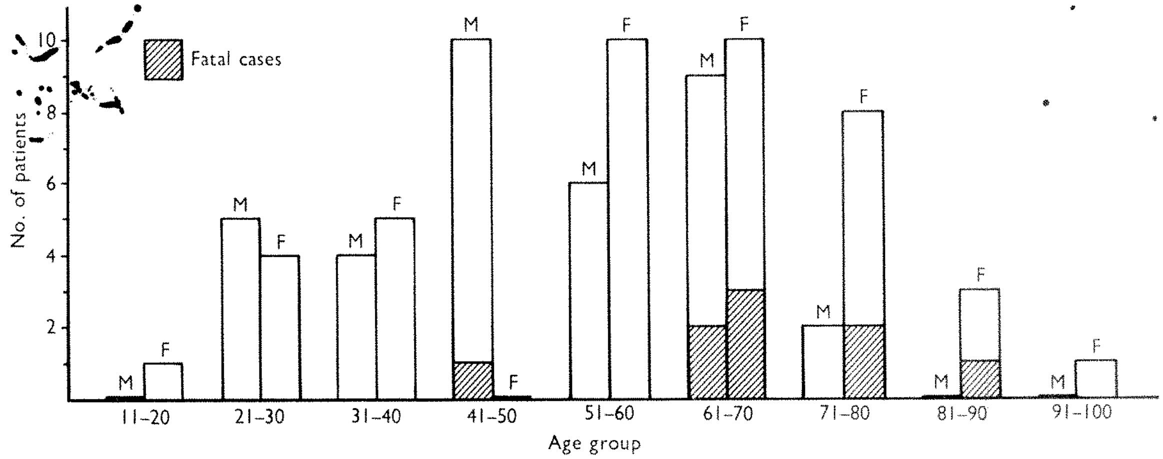

Fig. 1. Age and mortality of patients with acute pancreatitis.

Management

Each patient was seen at least daily by one of us. Management was by nasogastric suction and the administration of intravenous fluids. Pethidine (50–150 mg according to body weight) was the analgesic routinely used. Antibiotics and anticholinergics were not administered routinely.

Intravenous fluid replacement was based on normal saline, Ringer's lactate and dextrose solutions with the necessary addition of potassium and calcium supplements. Dextran solutions, plasma and blood were given on specific indications. Parenteral intravenous amino-acid and lipid solutions to provide calories were reserved for patients who required intravenous therapy for longer than 1 week.

If any doubt existed as to satisfactory urinary output, catheterization was carried out and hourly urine volumes monitored with the aim of maintaining a minimum level of output of 30 ml/hour. To achieve this, a high rate of intravenous infusion was frequently required. Central venous pressure was recorded during such infusion. Failure to ensure adequate urinary output was then treated by the intravenous administration of mannitol or frusemide.

Results

There were 36 male and 42 female patients in the study and 9 died (11·5 per cent mortality). All 9 deaths occurred in a group of 26 patients who met the criteria for severe disease. Only 6 per cent of those managed conservatively died, and 19 of this group of 67 patients were considered to have severe disease.

The younger patients (< 60 years old) had a much better prognosis than did the older patients (*Fig.* 1, *Table I*). A high incidence of biliary disease occurred in young females (*Table II*), while in young males a high incidence of alcohol-related pancreatitis was found (*Table III*). The only fatal case in this age group was a 41-year-old male with alcohol-related pancreatitis.

Patients over the age of 60 had a much higher mortality rate (*Fig.* 1, *Table I*), and in contrast to the young patients none was considered to have alcohol-related acute pancreatitis.

Up to 60 years	19	1
Over 60 years	0	0

Associated aetiological factors

The importance of identifying aetiological factors in acute pancreatitis has frequently been stressed because elimination of such factors may protect the individual patient from recurrent attacks.

Biliary disease

Forty patients (51 per cent of the total) had biliary disease (*Table IV*) and the mortality rate of this group was 12·5 per cent. Twelve were shown to have a common bile duct disorder, either stones or debris. The incidence of biliary disease is greatest in younger female patients, and for older patients the incidence for each sex is identical (*Table II*).

The results of elective surgery for biliary tract disease are shown in *Table V*. In the patient who had

Table IV: SUMMARY OF ASSOCIATED FACTORS

Table VI: MORTALITY IN RELATION TO OPERATIVE AND NON-OPERATIVE MANAGEMENT IN EARLY PHASE OF TREATMENT

		Mortality	
Treatment	Total	No.	%
Operative	11	5	45·5
Non-operative	67	4	6·0
Total	78	9	11·5

a postoperative recurrence, retained stones within the common bile duct were demonstrated on endoscopic retrocholedochopancreatography (Blumgart et al., 1972). Removal of these at a further operation has resulted in a symptom-free period of over 18 months. By contrast 5 of the patients not operated on electively died, and 2 of the survivors have suffered recurrent attacks of acute pancreatitis. One patient has been lost to follow-up and the remaining 2 are well.

Three of the 5 fatal cases had surgery performed while suffering from acute pancreatitis. Two had a laparotomy performed within 24 hours of hospital admission because of diagnostic uncertainty, and the third had cholecystectomy and common bile duct exploration performed 22 days after the onset of a prolonged attack of pancreatitis in an attempt to improve the course of the disease.

Alcohol

Twenty patients, all less than 60 years old, suffered acute pancreatitis within 36 hours of heavy alcohol intake. Only 1 patient in this group died. However, the recurrence rate was very high and of the 17 cases reviewed at follow-up, only 2 have been free from further attacks. Both have abstained from alcohol.

Other associated factors

Three patients experienced their first attack of acute pancreatitis within 3 months of parturition, but biliary disease was present in all 3.

It is of interest to note that there were 3 patients who had both a gastro-enterostomy and biliary disease. Another 3 were known to have coincidental duodenal ulceration and 1 of these was treated surgically at the same operation as elective cholecystectomy and exploration of the common bile duct. Pancreatic carcinoma was diagnosed in 2 patients who originally presented with clinical and biochemical evidence of acute pancreatitis. Finally, severe hypothermia (rectal temperature 29 °C) was present in 2 female patients on admission.

Idiopathic cases

There were 10 instances in whom an associated aetiological factor could not be defined. In this group 5 elderly patients were considered on radiological and clinical grounds to have probable, but not proved, biliary disease. No case of hyperparathyroidism or hyperlipoproteinaemia was identified. Acute and convalescent viral titres were estimated in several of this idiopathic group, and no elevated values recorded.

Postoperative pancreatitis

Four patients developed postoperative pancreatitis. Three, of whom 2 had been subjected to transduodenal sphincterotomy, were diagnosed in the immediate postoperative period. The third patient had a retained stone present after choledochotomy. All 3 had large volumes of postoperative nasogastric aspirate or vomiting, and in 2 severe upper abdominal pain was also present. Grossly elevated serum and urine amylase levels were found in all 3.

The fourth patient developed acute pancreatitis 7 days after surgery unrelated to the biliary tract. All of these patients survived.

Effect of early surgical intervention (*Table VI*)

Eleven patients had a laparotomy performed within 24 hours of emergency hospital admission because of uncertainty of diagnosis. Laparotomy was performed with or without tube drainage and only 1 of these patients had the additional prodecure of cholecystostomy performed. Five died (mortality 46 per cent). The period from diagnosis to death varied from 2 to 55 days, and additional factors contributing to death were present in most cases (*Table VII*). Similarly, in the 4 fatal instances within the group of patients managed conservatively additional factors were present and the deaths occurred from 10 to 70 days after admission (*Table VIII*).

Calcium and phosphate changes

Serum calcium levels examined retrospectively were found to have been associated with a poor prognosis, there being 7 deaths in 15 patients with calcium levels of less than 8·0 mg/100 ml. It was also noted that serum phosphate levels frequently fell below 2·0 mg/100 ml (14 patients), although only 5 patients had simultaneous falls in the calcium level below 8·0 mg/100 ml. Hypophosphataemia was transient and occurred on the second to fourth day after admission to hospital.

Transaminase elevations

Significant rises in serum transaminase levels occurred in 20 of the 67 cases in which they were measured. Elevations of transaminases were in most cases of a temporary nature, running a course parallel to the elevations of serum amylase. In every case one or both enzyme levels exceeded the upper limit of normal by at least a factor of 2·5. In only 12 of these 20 cases did bilirubin levels exceed normal values, but 17 of the 20 showed accompanying elevations in alkaline phosphatase.

Complications

Table IX lists the complications and their relation to the outcome. The adverse prognostic association of acute renal failure and gastro-intestinal bleeding (Trapnell, 1971) is clear.

Discussion

This study has demonstrated that good conservative management without the addition of specific drugs can be associated with a mortality rate of less than 12 per cent in acute pancreatitis. If operation is avoided, then this mortality can be reduced to 6 per cent. A further 62 patients have been studied during 1973 and confirm these views, the overall mortality for all the patients being 10 per cent. Even if patients with alcohol-related disease are excluded, then the mortality rate is 11 per cent and comparable to that recorded for high dosage trasylol treatment (Trapnell et al., 1974).

Factors which may have contributed to this reduced mortality are a low incidence of diagnosis by laparotomy in comparison with retrospective studies (Trapnell and Anderson, 1967; Imrie, 1974), early diagnosis because of clinical awareness, better methods of accurately measuring serum and urinary amylase concentration, an appreciation of risk from operations on the biliary tree and the personal care which comes from concentration on a problem. However, there remains room for further improvement in that in all the 11 instances of diagnosis at laparotomy the disorder had not been considered and amylase levels not ascertained. Before proceeding to laparotomy—which in our experience was associated with the death of nearly half those submitted to it—not only should amylase levels be determined but also consideration given to peritoneal aspiration through a dialysis catheter (Elliott, 1971). We have recently used this and determined the amylase and bacterial contents of the aspirate before a final decision on laparotomy.

Why patients die after laparotomy is not clear, but hypoxia may be important. Twenty-five of 34 of our patients in whom blood gas analysis was done within 24 hours of admission but before surgery had arterial P_{O_2} levels of less than 70 mm Hg, a finding already recorded by others (Ranson et al., 1973). Surgical exploration will only make such a disturbance worse.

A further lethal event in past series has been acute renal failure and although our incidence is low, our experience of the developed condition remains unsatisfactory with 4 out of 5 patients failing to survive. The wider use of peritoneal dialysis (Gliedman et al., 1970) may alter this gloomy outlook and we have recently successfully managed the pancreatitis and renal insufficiency of 2 patients in this way.

Table VII: SUMMARY OF THE PATIENTS WHO DIED OF ACUTE PANCREATITIS AFTER UNDERGOING LAPAROTOMY

Sex	Age	Major factors	Time of death (days from onset)
M	41	ARF; bacteraemic shock	9
M	69	Perforation of colon; faecal peritonitis	55
M	70	ARF; lung abscesses; severe diabetes; DVT + PTE	26
F	79	ARF; cerebrovascular accident	31
F	86	None known	2
Mean age 69			Mean 24·6

ARF, Acute renal failure. DVT, Deep vein thrombosis. PTE, Pulmonary embolism.

Table VIII: SUMMARY OF THE PATIENTS WHO DIED OF ACUTE PANCREATITIS WHICH WAS TREATED CONSERVATIVELY

Sex	Age	Major factors	Time of death (days from onset)
F	62	None known	28
F	65	Pleural effusion; diffuse haemolysis	70
F	66	ARF; lung abscess; gross hypothermia; CCF	12
F	79	Bacteraemic shock	10
Mean age 68			Mean 30

ARF, Acute renal failure. CCF, Congestive cardiac failure.

Table IX: COMPLICATIONS OF ACUTE PANCREATITIS

Complication	No. of cases	% of total	No. of deaths
Acute renal failure	5	6	4
Pseudocyst	4	5	—
Diabetes	4	5	1
Pancreatic abscess	3	4	—
Gastro-intestinal bleeding	3	4	2
Wound dehiscence	3	4	—
Postoperative fistula	2	3	—
Pleural effusion	2	3	1

No previous British survey of acute pancreatitis has revealed such a high incidence of alcohol-related cases, although a similar incidence was reported from Edinburgh hospitals (Gillespie, 1973). An overall increase in alcohol intake is reflected in a 12 per cent incidence of alcohol-related acute pancreatitis in England (Trapnell, 1972), and an increased incidence of alcohol-related chronic pancreatitis (James et al., 1974).

A high proportion of alcohol-related cases in any particular group studied may contribute to a lower mortality (Gliedman et al., 1970). However, it is noteworthy that in the present study none of the patients with alcohol-related pancreatitis was over 60 years old, while 53 per cent of the patients with biliary disease were over this age. It is therefore possible that the different age groups of the patients, rather than the different aetiological factors, may be of greater importance in determining the mortality rate for these two groups. Because of our ability to relate the disease to causes such as alcohol, we have only a few idiopathic cases, in contrast to others (Sarles et al., 1965; Trapnell, 1966). We have confirmed that elective biliary surgery will prevent recurrence of pancreatitis, and that careful exploration of the common duct yields a 30 per cent incidence of stones and debris.

Evaluation of laboratory results has revealed two other matters which have received little previous attention in addition to the well-known relationship between hypocalcaemia and poor outlook. First, a quarter of our patients had elevated transaminase levels, as did those of one other series (Lukash, 1967), and only two-thirds of these had synchronous rises in bilirubin concentration. Secondly, the profound fall in phosphate levels has not previously been recorded. The most severe degrees of hypocalcaemia were not invariably linked to these changes in phosphate levels, but nevertheless falls in the level of ionic calcium may be the stimulus to increased parathormone release resulting in phosphaturia. This hypothesis must await reliable assays for parathormone in addition to measurements of ionic calcium levels in these patients.

In conclusion, it is clear that there are no obvious differences between the mortality rate of primary acute pancreatitis managed conservatively as in this study and the published results of management which includes high dosage treatment with Trasylol or glucagon.

Acknowledgements

We thank the consultants of the surgical and medical divisions of Glasgow Royal Infirmary for their cooperation and permission to study cases under their care. Particular thanks are due to Professor L. H. Blumgart for his help and constructive criticism during the preparation of this paper. A study of this type would be impossible without the great assistance of the nursing staff in collecting the essential urine specimens and of the many housemen who helped in taking blood specimens. We thank these members of staff and also those of the Biochemistry Department for invaluable help.

The use of the vas deferens in inguinal herniorrhaphy

PATRICK SAMES*

SUMMARY

A new method of repair of inguinal herniae is described using the vas deferens as a suture material. It is especially suitable in very large and recurrent herniae. Nineteen cases have been operated on in this way with an average of 38 months' follow-up. In none has recurrence been noted. It is suggested that the vas deferens, so readily to hand, forms a more natural barrier than man-made fibres. It may also, in fact, remain viable, though this has not, as yet, been proved.

THE surgical repair of very large and recurrent inguinal and inguinoscrotal herniae still presents a considerable problem. In the past a variety of suture materials has been used with differing results. These materials fall mainly into two groups; some form of man-made fibre, and those occurring naturally and being an integral part of the body. Darning with such substances as floss silk (Maingot, 1941) or the insertion of woven barriers of wire (McGavin, 1909) or twisted silk (Handley, 1918) has had its advocates. However, a common failing with these is the high incidence of sepsis and sinus formation, sometimes quite late in the postoperative period and occasionally necessitating a most difficult operation for the removal of the foreign substance. The advent of monofilament nylon (Moloney, 1948) considerably improved the outlook, as this substance is less likely to give rise to postoperative sinus formation, unlike its woven and multifilament counterpart. At present some form of darning operation using monofilament nylon is probably the most widely practised procedure.

The most popular operation making use of naturally occurring material is that described by Gallie and LeMesurier (1921) whereby strips of fascia lata are taken from the thigh. These are usually obtained by the use of a fasciatome but leaves the patient with an unfortunate herniation of thigh muscle through the fascial defect. Although this does not materially affect function, it is cosmetically undesirable; it has, in fact, been the basis of litigation against the surgeon. This herniation can, of course, be avoided by taking the fascia by open operation and resuturing the defect, but this then becomes a major procedure in itself. Attempts have been made to use strips of the external oblique aponeurosis at the site of the operation (McArther, 1904), but this structure is often very poorly developed in large or recurrent herniae. Free strips of skin from the edges of the incision have also been used (Mair, 1945), but have the disadvantage that inclusion dermoid or sebaceous cysts have occurred later in the depth of the wound.

Another and hitherto unexplored source of naturally occurring material available for the repair of herniae is the vas deferens, as suggested by the author in a previous communication (Sames, 1968). This structure has the advantage of being readily to hand, and is already fixed at its proximal end. The whipcord-like structure has a greater diameter than nylon and therefore fills in the fascial and muscle defects with greater certainty. In the elderly with very large and difficult herniae the testis and cord may be sacrificed, provided always that the patient has given his consent. Even when the testis is preserved, the patient's consent should be obtained as for vasectomy. This step is even more cogent should it be contemplated that bilateral herniae are to be repaired in this manner.

Technique

After the sac has been freed and dealt with in the usual manner, the vas deferens is traced down to the lower pole of the epididymis and divided at the point where it starts to become tortuous. The average length measured from high in the internal inguinal ring to the point of section is 26 cm (*Table I*). There is a marked variation in the diameter of the vas, which tends to be thinner in older subjects, although the reverse is sometimes the case. No attempt is made to clean off the flimsy integument from the vas as it is possible that the fine vessels on the outer aspect of the wall may stay intact and the vas remain viable. Unfortunately the author has not had the opportunity to confirm this by autopsy examination. In a very large direct hernia the bulging of fat and peritoneum can usually be controlled by suturing what is left of the transversalis fascia with interrupted cotton sutures. When this is not practical the use of a damp swab and narrow-bladed depressor should suffice.

When using the vas, in contradistinction to nylon darning, the repair commences at the outer end of the canal because the vas is already fixed here within the pelvis. In large saddle-backed herniae it is wise to divide the deep epigastric vessels between ligatures. The vas is too fat to thread even on to a Gallie's fascial needle, therefore suturing is carried out by pushing a Cleveland ligature carrier or fine-pointed mosquito forceps through the relevant structures, grasping the divided end of the vas and drawing it through. At the commencement the vas is brought out of the pelvis by piercing the internal oblique muscle just lateral to the ring, and then proceeding medially to fill in the gap between the inguinal ligament below

17	56	35	No	39	
18	76	28	Yes	12	Associated large hydrocele

and the conjoint muscle and tendon above. Great care should be taken to continue the repair far into the medial angle, to the region of the pubic tubercle below and the fascial sheath of the pyramidalis or rectus muscle above.

In very large and long-standing inguinoscrotal herniae there is usually marked hypertrophy of the integument of the cord, especially the cremasteric muscle. A decision must therefore be made whether or not to include this structure in the repair. When it is to be preserved it must be trimmed to give a 'skirt' both above at the lower border of the conjoined muscle and below at the lower border of the inguinal ligaments before including it in the buttress repair. In some subjects these fasciae are only an embarrassment and as such are best sacrificed. It is vital in all cases that such clearance be made at the innermost angle in order to define properly the medial end of the inguinal ligament, the fascia over the rectus or pyramidalis muscle and the pubis tubercle. There are often numerous veins in the floor of the canal going to the scrotal skin (veins of Tasker); these should be carefully cleaned away.

When the darn is completed the free end of the vas is fixed with an interrupted cotton suture. There is usually a surplus of 2–5 cm remaining. This is then woven back on itself, passing under one strand and over the next until finally used up. The end is securely anchored with another interrupted suture. Care must be taken, when suturing down to the inguinal ligament, to pierce it at slightly different levels to avoid splitting the strands. The repair should be strictly a loose darn and no effort should be used to draw the tissues together. The external oblique aponeurosis is either repaired over or behind the cord according to local circumstances and the particular practice of the surgeon. It is wise, especially in moist cases, to drain the depth of the wound or scrotum with a Redivac suction drain.

Results

These are as shown in *Table I*. Nineteen patients have been followed up for an average of 3½ years and in none has recurrence been noted; no patient has been lost to follow-up. Wound infection occurred in 1 case, but this presented in a man who while waiting for his operation, and on a strict dieting régime, had developed signs of strangulation. He was, in fact, a mild diabetic, standing only 1·6 m high and weighing 140 kg. The repair was associated with an excision of his dewlap weighing 4 kg and of omentum weighing 3 kg. The sepsis was confined to the opposite side from his hernial repair and was no doubt associated with the moist intertrigo noted before the operation.

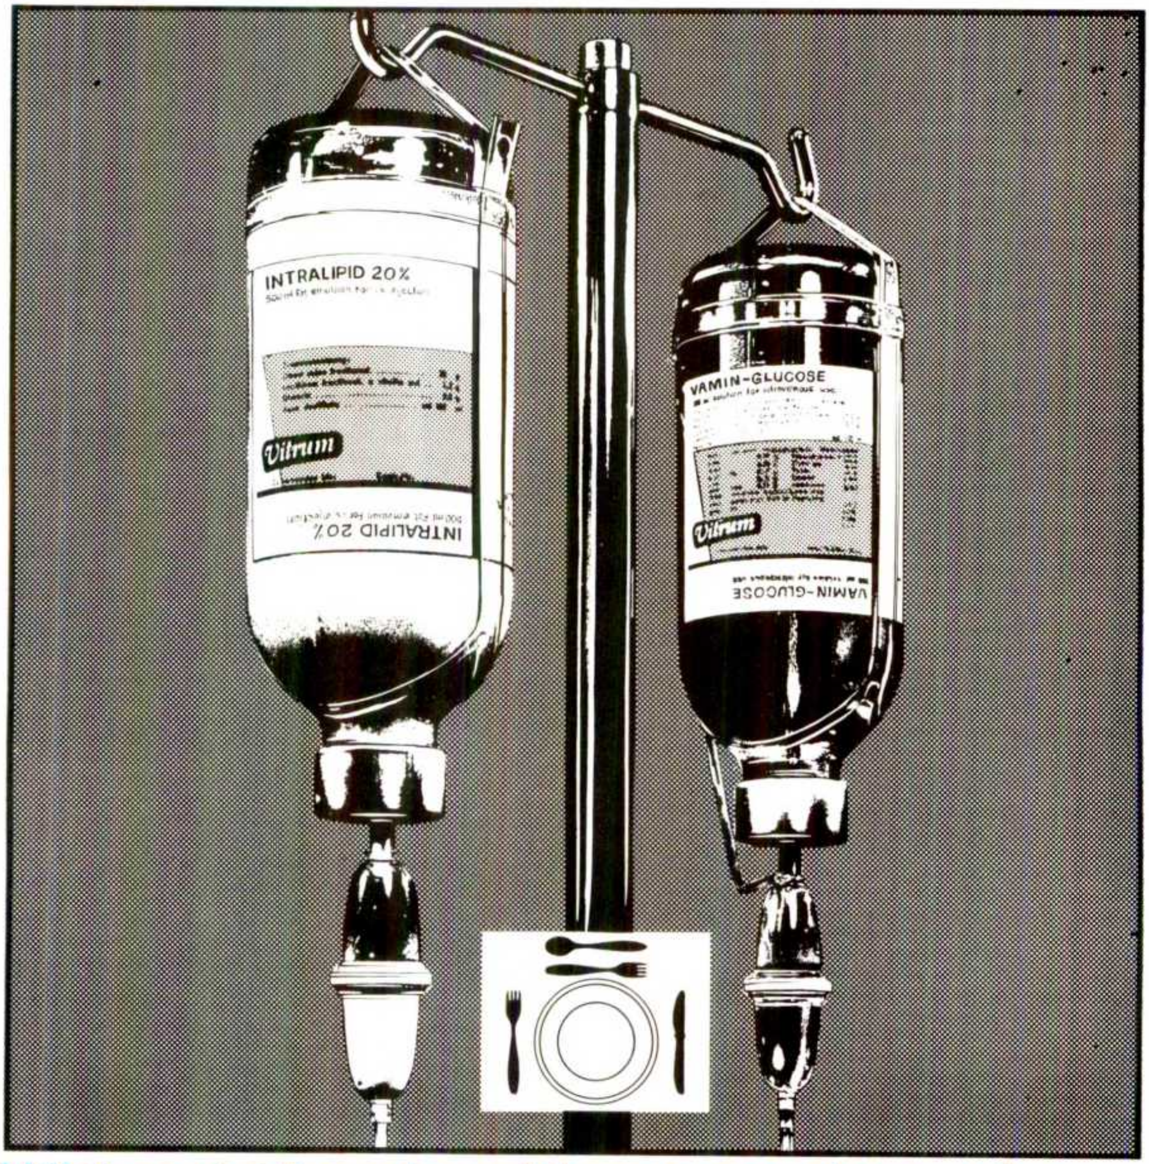
SEPTRIN contains trimethoprim and sulphamethoxazole.
Full prescribing information is available on request.
Wellcome Medical Division.
The Wellcome Foundation Ltd.,
Berkhamsted, Herts.

When clinical examination reveals urinary infection in children, experience increasingly indicates the need for the prompt, vigorous action of SEPTRIN Paediatric Suspension.

Rated top oral treatment in a British survey of 23,491 urinary pathogen sensitivities,[1] SEPTRIN has been judged superior to ampicillin,[2,3] and is now well established as a first-line treatment for urinary infections.



With nutritional problems you always have solutions . . . *Vitrum* solutions

TOTAL PARENTERAL NUTRITION aids patient recovery. Improves wound healing. Increases resistance to infection. Fosters earlier discharge from hospital.

When the gastrointestinal route is inoperative nutrients must be supplied directly into the bloodstream. The total range of Vitrum solutions meets this requirement totally. Vitrum provides Total Parenteral Nutrition, in the forms and quantities naturally transferred to the bloodstream after digestion of normal food.

The body's requirement of aminoacids, the building stones of proteins, carbohydrates and electrolytes is provided by VAMIN and AMINOSOL solutions.

The requirement of energy, fat, essential fatty acids and phosphorus is provided by INTRALIPID.

VAMIN and AMINOSOL contain all the 18 aminoacids required for protein synthesis – essential, semi-essential and non-essential – in the physiological L-form.

✲Vamin/Glucose ✲Vamin-Fructose ✲Vamin "N"
✲Aminosol 10% ✲Aminosol/Glucose
✲Aminosol/Fructose-Ethanol
✲Intralipid 10% ✲Intralipid 20%

Nitrogen mustard as adjunctive chemotherapy for breast carcinoma

JAMES R. HINES AND JOHN S. WILLIAMS

SUMMARY

A retrospective study is reported of 38 patients with breast carcinoma treated by radical mastectomy and a short course of nitrogen mustard. They were followed up for an average of 10 years. There were no serious untoward reactions to the drug. The 5- and 10-year corrected survival rates were 74 and 71 per cent respectively. There would appear to be a renewal of interest in adjuvant chemotherapy for patients with breast carcinoma.

POSTOPERATIVE adjunctive chemotherapy for patients with breast carcinoma is being reappraised. There have been at least 32 different studies using single drugs or combinations of drugs as adjuvant treatment in patients with 'surgically resectable' breast cancer and many new studies are in progress (Tormey and Geelhoed, 1975). Impetus for improved primary treatment of breast carcinoma comes from disappointment in the results of extended operations, pre- and postoperative irradiation, prophylactic oophorectomy and exogenous hormones. Immunotherapy has not yet had a significant impact as it is just beginning to be tried clinically.

While new trials using adjuvant chemotherapy are being started, there is a need to examine the results of earlier work in this area. This study reviews retrospectively the records of 38 patients who received a short course of nitrogen mustard as an adjuvant to radical mastectomy. These patients have been followed up for an average of 10 years. We can find only one other series in the English literature in which nitrogen mustard was used as the sole adjunctive chemotherapeutic agent in patients with breast carcinoma.

Patients and methods

The 38 female patients in this study had 'surgically curable' breast carcinoma as there were no cases with skin ulceration, chest wall fixation, fixed axillary nodes, distant metastases or inflammatory carcinoma. The ages of the patients ranged from 30 to 72 years, the average being 55 years. None of these patients had a serious associated medical illness. The size of the primary tumour ranged from 1 to 10 cm in greatest dimension, the average being 3 cm. All the tumours were adenocarcinoma of ductal origin. Thirteen of the 38 patients had one or more positive axillary lymph nodes.

All the patients were subjected to a standard Halsted radical mastectomy. The wounds were washed with a 50 per cent sodium hypochlorite (Dakin's) solution prior to skin closure in an effort to reduce local recurrence. Nitrogen mustard was given intravenously during the operation and on the first 2 postoperative days. The total dose was 0·4 mg/kg and each patient received an average of 7 mg a day for 3 days. Leucocyte and platelet counts were taken daily in 34 of the 38 patients. Patients with positive nodes received postoperative irradiation to the axillary, internal mammary and supraclavicular areas, the average total dose being about 7000 rad. Five patients, all premenopausal, were subjected to prophylactic oophorectomy shortly after mastectomy.

The postoperative follow-up was from 7 to 15 years, the average being 10 years. One patient was lost to follow-up after 50 months, but all of the others have been traced.

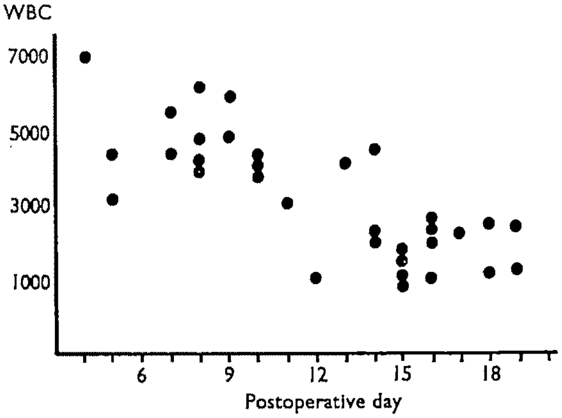

Fig. 1. Serial leucocyte counts in patients receiving NH$_2$ following mastectomy. Each dot represents the lowest count of a patient and the postoperative day that it was recorded.

Results

None of the patients in this series developed complications directly attributable to the chemotherapy. There were no deaths or serious postoperative morbidity. Wound problems occurred in 12 of the 38 patients (32 per cent). These were fluid collection in 6 patients, heavy crusting of the skin edges with slow healing in 3 patients, necrosis of skin requiring grafting in 2 patients and scar formation requiring plastic correction in 1 patient. These complications are similar in type and degree to those found in most series of patients with radical mastectomy with chemotherapy (Cohn et al., 1968). No significant depression of platelet counts was noted. Leucocyte depression was common, the lowest count being 900/ml. The lowest white blood cell counts were from the twelfth to the

Table I: HISTOLOGY OF THE TUMOURS

Tumour type	No. of patients	No. died
Poorly differentiated scirrhous carcinoma	16	4
Poorly differentiated adenocarcinoma	5	3
Well-differentiated scirrhous carcinoma	4	0
Well-differentiated adenocarcinoma	3	1
Poorly differentiated mucinous carcinoma	2	0
Well-differentiated medullary carcinoma	2	0
Well-differentiated mucinous carcinoma	1	1
Well-differentiated intraductal carcinoma	1	0
Undifferentiated carcinoma	1	1

Table II: NODAL STATUS OF THE PATIENTS

No. of positive nodes	No. of patients	No. died	% survived
0	24	3	87·5
1–3	2	1	50
4 or more	9	6	32

eighteenth day and the average count on the fifteenth postoperative day was 2030/ml (*Fig.* 1). After this time a gradual rise toward normal was seen and the counts had returned to normal by the thirtieth day. Reverse isolation was used when the white cell count went below 2000/ml.

One patient was lost to follow-up at 50 months. At that time she was clinically free of her tumour. Two patients died of unrelated diseases, one at 34 months and one at 50 months; both patients were clinically free of breast carcinoma at the time of their death. Thus, 35 patients were available for long term follow-up. Two patients developed carcinoma in the opposite breast, one at 6 years and one at 7 years. Both are still alive 5 and 7 years later, following a second mastectomy. Local skin recurrences were detected in 2 patients, one at 1 year and one at 4 years. The first patient is still alive 7 years later, but the second died of disseminated disease. Two patients developed isolated bone lesions presumed to be metastases, one in a pelvic bone 4 years after mastectomy and one in a rib 4 years after mastectomy. Both were treated by irradiation and are alive 6 and 7 years later respectively. Four of the 5 patients subjected to prophylactic or adjunctive oophorectomy are alive and well. Two of these patients had the isolated bone lesions.

Ten of the 35 patients followed up died of breast carcinoma. The other 25 patients (71 per cent) are alive and clinically free of breast cancer at this time. Of the deaths, 9 patients died within 5 years and one died 10 years following mastectomy. The average time from mastectomy to death was 42 months. The patients with the more undifferentiated tumours had a somewhat lower rate of survival (*Table I*). The patients with positive lymph nodes had a markedly reduced survival rate (*Table II*).

The crude 5-year survival rate was 68 per cent and the adjusted 5-year survival rate was 74 per cent. The crude 10-year survival rate was 65 per cent and the adjusted 10-year survival rate was 71 per cent.

Discussion

The principle of adjuvant chemotherapy is based on two experimental observations. In animals, cure of implanted carcinoma has been achieved following subtotal tumour resection and simultaneous administration of chemotherapeutic agents. In addition, chemotherapeutic agents were effective in preventing the 'take' of injected tumour cells (Cruz et al., 1956; McDonald et al., 1956, 1957). Circulating tumour cells have been demonstrated in the bloodstream of patients with various forms of malignancy. The number of these tumour cells increases during periods of surgical manipulation (Roberts et al., 1961; Evans and Scott, 1969). The objective of adjuvant chemotherapy is both the prevention of implantation of circulating tumour cells and the possible eradication of early metastases.

During the mid-1950s many investigators began clinical trials of adjuvant chemotherapy in the surgical treatment for breast carcinoma (Shimkin and Moore, 1958; Holland, 1961; Roberts et al., 1961; Noer, 1963; Fisher et al., 1968; Donegan, 1970; Mrazek and McDonald, 1970; Nissen-Meyer, 1970; Finney, 1971; Fisher, 1971; Nissen-Meyer et al., 1971; Donegan, 1974). Results varied from markedly optimistic, especially during the early phases of the studies (Mrazek and McDonald, 1970), to those showing decreased survival and increased recurrence compared with control groups (Finney, 1971). In most of the studies single agent, short-term, postmastectomy chemotherapy did little to alter the long-term survival in breast carcinoma. The major investigation, undertaken by the National Institutes of Health National Surgical Adjuvant Breast Project (NSABP) involving 23 separate institutions over a 10-year period, was reported by Fisher et al. in 1968. A total of 1341 patients in the project received thiotepa, 5-fluorouracil or a placebo. They found that a 3-day course of postoperative thiotepa to be of benefit only to premenopausal women with four or more histologically positive axillary lymph nodes. The 5-year survival rate in this group was 58 per cent, and was 25 per cent in the controls. They also found that thiotepa seemed to have the same inhibitory effect on local recurrence that is seen with postoperative radiotherapy.

Tormey and Geelhoed (1975) quoted a Russian study reporting a lowered recurrence rate following 2 weeks of postoperative thiotepa. They also reported that a German study using oral cyclophosphamide for 2 months effectively reduced recurrence, and a study from a Scandinavian group using cyclophosphamide also gave good early results. Mrazek and McDonald (1970) gave nitrogen mustard at the time of operation and every 3 months for several courses of treatment. They found a reduced recurrence rate, especially in premenopausal patients with negative axillary nodes. This is the only study we have found in which nitrogen mustard was used as the sole adjuvant drug in the primary treatment of breast carcinoma.

The long term use of adjuvant chemotherapy with thiotepa has been reported by Long et al. (1969) and Donegan (1970, 1974). They gave weekly injections and have reported a trend towards improved survival in patients with negative axillary nodes. The NSABP is organizing a trial of long term chemotherapy with phenylalanine nitrogen mustard as an adjuvant to radical mastectomy in patients with four or more positive axillary nodes (Fisher, 1972).

Combination chemotherapy has had encouraging results in patients with metastatic breast carcinoma (Carter, 1972). Protocols for adjuvant chemotherapy with a combination of drugs are being developed by several groups including the Eastern Oncology Group, Acute Leukemia Group B, the Mayo Clinic and Berto Verici in Milan. Another intriguing possibility that has been suggested is the combination of chemotherapy and immunotherapy. Chemotherapy would serve to decrease the number of tumour cells prior to the initiation of immunotherapy (Fisher, 1972).

The current study of 38 patients is too small to provide evidence for or against adjuvant chemotherapy in breast carcinoma. The 71 per cent survival rate with an average follow-up of 10 years is above the average 5- or 10-year survival rates (Butcher, 1961; Goldenberg et al., 1961). This survival rate may have been favourably influenced by aggressive postoperative follow-up care. The incidence of complications in this series was no greater than that seen in patients having radical mastectomy without chemotherapy, and there was no significant patient discomfort or increased hospital stay associated with the treatment. While the use of nitrogen mustard did not prevent the use of other forms of adjuvant therapy—irradiation and oophorectomy—it has the potential for causing serious untoward effects.

Nitrogen mustard (mustargen hydrochloride, NH$_2$) is the parent compound of all the alkylating agents and one of the first chemotherapeutic agents found to be effective against tumour cells. Alkylating agents affect tumour cells (and to a lesser extent normal cells) by disturbing DNA synthesis during cell division through a process of misreplication of the DNA chains (Finney, 1971). HN$_2$ has the disadvantage of requiring intravenous administration because of its vesicant properties, but this caused no problem in the present series as all the patients were hospitalized and were given a short course of treatment. NH$_2$ has been shown to be effective in the treatment of metastatic breast carcinoma (Holland, 1961; Carter, 1972). Immediate undesirable reactions of NH$_2$ include anorexia, nausea and vomiting. Long term untoward effects include leucopenia, thrombocytopenia, allergic rash, infection with herpes zoster and menstrual irregularities. Phlebitis, skin slough and severe brawny induration have been seen following local infiltration of the drug. Nitrogen mustard can cause serious problems. A patient in our institution died of leucopenia and thrombocytopenia following its administration as adjuvant chemotherapy. In a nearby hospital a subcutaneous extravasation of NH$_2$ caused a skin slough that required extensive skin grafting. While the untoward effects of nitrogen mustard have limited its use as an adjuvant agent, the studies using this drug are so few that we feel even this small series should be reported.

The value of adjuvant chemotherapy in breast carcinoma is not known. Bernard Fisher, one of the principal investigators in the NSABP study, feels that the trials to date do not repudiate the value of adjuvant chemotherapy, but simply provide 'no test' (Fisher, 1972). Because of increased understanding of tumour pathology, tumour–host relationships, the mechanism of chemotherapeutic agents and the development of new drugs, new trials should be undertaken. While renewed interest appears warranted, it is still an experimental procedure. Only by well-planned, cooperative, prospective clinical trials can the value of this treatment be obtained in a reasonable period of time. Surgeons should join these trials if there is a possibility of long term benefit to the patients and the treatment has a low incidence of toxicity. Dr Douglas C. Tormey, Chief of the National Cancer Institute's Medical Breast Cancer Service, said in March 1974: 'Current estimates suggest that micrometastases are present with a breast mass' and that animal studies strongly suggest 'it is much easier to eradicate early micrometastases than it is for them to become clinically manifest'.

Reviews and notices of books

Functional Anatomy of the Digestive System
R. M. H. McMinn, London, and M. H. Hobdell, London. 240×185 mm. Pp. 239+xi. Illustrated. 1974. Tunbridge Wells: Pitman Medical. £2·90.

MODERN preclinical education has two important features. First, it tries to break down the rigid barriers between the various disciplines which make up the student's curriculum; this simplifies and rationalizes the enormous amount of material he must ingest during his undergraduate career. Secondly, it attempts to select and emphasize the topics which the student is going to need in the clinical part of his course and in his subsequent career. This volume achieves both these commendable targets. It considers the digestive tube and its adnexa from anatomical, histological, developmental and physiological aspects, emphasizing wherever possible the practical applications of basic sciences. In the section on the mouth, the teeth have been considered in some detail for the benefit of dental students, Dr Hobdell being an experienced teacher of dental anatomy. The text includes descriptions of surface markings, normal radiography and the techniques of investigating the various components of the alimentary tract. The book is clearly written and produced, and is copiously illustrated by line diagrams, together with histological and electron-microscopic photographs.

This is a book which can be recommended without hesitation to medical and dental students. The reviewer's only regret is that it was not available to him 31 years ago. HAROLD ELLIS

Atlas of Human Anatomy. Volumes 1, 2 and 3
Edited F. H. T. Figge and W. J. Hild. Ninth English edition. Based on the seventeenth German edition edited by H. Ferner and J. Staubesand. 250×200 mm. Pp. 275+xvi, 245+xvi and 357+xx, with 365, 315 and 443 illustrations respectively. 1974. München: Urban & Schwarzenberg. DM 75, 75 and 85.

THIS is the ninth edition in English of the *Atlas of Human Anatomy*, largely supervised by Professor F. H. T. Figge of Baltimore before he died and completed in the emergency by Professor W. J. Hild of Galveston. There is a companion seventeenth edition in German.

The continued popularity of this book speaks for itself. The English edition is obviously more used in America than in the United Kingdom and this is a measure of the curtailment of work in American dissecting rooms and an indication of how most anatomical museums have been transformed into laboratories devoted to ultrastructure and not to gross structure. There are sufficient plates of different levels of exposure in most regions to make the surgeon familiar with what to expect as the way opens up before his scalpel.

Without doubt the price will deter most British undergraduate students, but the book's continued presence in college libraries and postgraduate centres will ensure its justified popularity.

Volume 1 is concerned with the locomotor system in general. There could probably have been more X-rays of bones and joints and ossification is rarely mentioned. The diagram of the muscle attachments in the hand (*Fig.* 326) is difficult to follow, but that of the foot (*Fig.* 354)—well, words fail.

Volume 2 is concerned with visceral anatomy. Variations in shape and position are illustrated with X-rays, and the surgeon will find the illustrations of the commoner arrangements of the extrahepatic biliary system useful. The X-rays are of a very good standard and are well reproduced. Some are unusual, as of the seminal vesicles and the ducti deferentia viewed against an air-filled urinary bladder! The three-dimensional low power histological photomicrographs of the wall of the different regions of the alimentary tract are very helpful.

Volume 3 is concerned with the nervous system, skin, etc. This volume contains an Errata insert—mostly of names which had not been changed from the Latin or the German into English. Brain plates are very standard. The diagrams of cortical localization by Brodmann and by Foerster have been retained and there are summaries of the main afferent and efferent pathways. The section on the autonomic nervous system is short and not very helpful. There is a jungle of sympathetic fibres. The cranial parasympathetic ganglia are shown along with the peripheral nerves. The pelvic parasympathetic nerves could not be found anywhere.

J. T. AITKEN

Endoscopy of the Small Intestine with Retrograde Pancreatocholangiography
Edited L. Demling and M. Classen, Erlangen. 230×155 mm. Pp. 143+xi, with 114 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.38.

THE ideas formulated at the International Workshop on Enteroscopy in July 1972 at Erlangen are recorded in this book in abridged form.

The first part of the book deals with the duodenum and papilla of Vater. This opens with a helpful paper on the diagnosis of duodenal ulcer with various fibrescopes and goes on to discuss questions in non-ulcer duodenopathy ('duodenitis'). Some more unusual subjects are then discussed, such as islands of gastric mucosa in the duodenum and malignant tumours of the upper small intestine.

The second part of the book is concerned with the pancreas, with the technical problems of retrograde pancreatography and the difficulty in diagnosing tumours and chronic pancreatitis. There are useful papers on evaluation of angiography and pancreatography in radiological diagnosis of pancreatic diseases, and an interesting article on duodenoscopic collection of intraductal pure pancreatic juice and its application to cytodiagnosis. There is also a paper on the hazards of endoscopic retrograde cholangiopancreatography. The brief paper on endoscopy in the diagnosis of obstructive jaundice is particularly useful. Inspection of the small bowel from above and below is adequately dealt with.

Progress of endoscopy in the past 10 years has been truly remarkable and this book represents a useful summary of the present position. IAN MCCOLL

Abdominal Echography. Ultrasound in the Diagnosis of Abdominal Conditions
E. Barnett and P. Morley, Glasgow. 216×140 mm. Pp. 138+x. Illustrated. 1974. London: The Butterworth Group. £4·50.

THIS little paperback book encompasses the immense experience of the authors in the art of sonar techniques. The illustrations almost exceed the text in quantity and are masterpieces of clarity. The techniques of obtaining ultrasonograms and the basis for interpreting them are made clear in a way which leaves the reader with no lingering doubts. The diagnostic uses available to the gynaecologist, obstetrician, internist, general surgeon and urologist are all concisely covered. Every new subject produces its own terminology and a useful glossary is provided to help and instruct the beginner.

Now that higher qualifications in diagnostic radiology demand knowledge of sonar methods, aspirants would be well advised to take the opportunity of assimilating the knowledge here presented in such palatable form. Considering the very large number of illustrations the price of this book must be regarded as reasonable. IAN DONALD

General Ophthalmology

Daniel Vaughan, San Francisco, and Taylor Asbury, Cincinnati. Seventh edition. 260 × 180 mm. Pp. 334. Illustrated. 1974. Los Altos, California: Lange Medical Publications. $9.50.

THE seventh edition of this interesting book is of value to medical students in that a wide range of ocular disorders is described, albeit in most instances briefly. This brevity of description detracts from the quality of the book as it must leave too many questions unanswered, even for medical students. For consultant and trainee ophthalmologists the book is not of academic interest. The illustrations, all in black and white, are excellent and numerous and give the reader a clear view of the disorder. There are abundant line drawings which are utilized to augment the text and they are particularly welcome in the anatomical introduction to chapters. In the appendices, of which there are three, the second contains good descriptions of common ophthalmic drugs which the student will find helpful, while the tables should also aid memorization of their contents. It is perhaps a pity that a longer description of the Goldmann perimeter and the interpretation of its fields are not included. The reasonably up-to-date text is clearly printed in double columns on good quality paper.

I. M. DUGUID

Safe Central Venous Nutrition. Guidelines for Prevention and Management of Complications

Mohamad H. Parsa, José M. Ferrer and David V. Habif, New York. 230 × 150 mm. Pp. 266+xi, with 131 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. No price given.

THIS book describes the experience of the authors of intravenous feeding at the Harlem Hospital during a period of 4 years. A central venous catheter was inserted 3059 times in more than 2000 patients of whom 400 were fed in this way with solutions of amino-acids or a protein hydrolysate and dextrose solution; fat was not used because it was not available in the United States at the time. They describe their techniques for the insertion of catheters into various veins and the treatment of the complications that they caused. There are a number of diagrams and photographs of the methods of inserting a cannula into the subclavian and other veins, but it is a pity that the operator only wears gloves and does not emphasize the strict aseptic precautions which seem desirable if infection is to be reliably prevented. The complications are listed; they occurred at a rate of 3·53 per cent per catheter, and of the 41 due to infection, septicaemia occurred in 36. Of the 118 references, 85 per cent were published in North America. There is no discussion at all of the use of fat emulsions and this serious omission greatly reduces the value of this book to those who work in countries where commercial fat emulsions are available. Moreover, the practice of transferring solutions from one bottle to another and of adding vitamins and electrolytes which is illustrated as well as described is contrary to the Federal Drugs Administration's hallowed and good principle of 'sterile in the final container'. There is useful information in this book but it is otherwise of limited value to the British reader.

A. W. WILKINSON

Chirurgie der Gegenwart

Edited R. Zenher, München, F. Deucher, Aarau, and W. Schink, Köln. 260 × 180 mm. Vol. 1, pp. 11, 22. Vol. 3, pp. 64, 34, 37. Vol. 4, pp. 46, 46. Illustrated. 1974. München: Urban & Schwarzenberg. No price given.

FURTHER chapters of this multivolume loose-leaf surgical text have now appeared. Carstensen has written about acid base balance and Bregulla and Ober have contributed a most useful chapter about the relationship between general surgical conditions and pregnancy. Accidents, appendicitis, hernias and other problems associated with pregnancy are discussed and treatment is evaluated.

In the orthopaedic volume Weber discusses the treatment of trauma to the ankle and the proximal part of the foot. Wstrow considers injuries to the nose and frontobasal fractures and the latter chapter has an up-to-date list of references.

Volume 3 dealing with thoracic surgery has also appeared and the first chapters include diagnostic measures, the surgery of the mediastinum and benign tumours of the lungs. All the chapters are exceedingly well illustrated and Professor Zenker and his colleagues should be congratulated on the speed with which the chapters of this mammoth work are appearing. The final assessment must await the completion of these seven volumes.

H. B. ECKSTEIN

Corticosteroid and ACTH Treatment. Principles and Problems

A. B. Myles, Surrey, and J. R. Daly, London. 226 × 115 mm. Pp. 216+viii. 1974. London: Edward Arnold. £4·75.

THIS is a well-written and readable book that in only 200 pages gives sufficient information about the chemistry, physiology and pharmacology of corticosteroids and corticotrophin to enable doctors to treat their patients with awareness of the problems involved in their use.

Various minor disagreements with the text could be mentioned, e.g. is the zonation of the human adrenal cortex really as clearcut as is suggested (p. 20)? Labelled cortisol should not be given by mouth for measurement of secretion rate (p. 31). Tetracosactrin tests should be performed at 8–10 a.m., when plasma cortisol is high (p. 40). More serious objection could be made to the use of dextrose–saline solutions in the treatment of adrenal insufficiency. These patients are depleted of extracellular fluid and have difficulty in excreting water. They must therefore be given 0·9 per cent sodium chloride solution and may require large volumes, e.g. 10 litres, to restore their volume depletion. The addition of deoxycorticosterone does not really help in these circumstances; recovery is quicker if more frequent (i.e. 4-hourly) intravenous injections of hydrocortisone sodium succinate are given.

In the section on treatment the authors correctly stress the efficiency of glucocorticoids in the early stages of rheumatoid arthritis and the danger of its use in the later stages where the physician may find himself trapped into giving larger and larger doses to relieve pain, with the eventual development of serious complications. In these circumstances other forms of treatment should be sought, although these also have their risks. Little exception can be taken to their suggestions for the management of patients with various diseases in which caution is shown in their advice as to dosage and awareness as to the effects of prolonged overdosage.

Overall, a volume giving adequate background to the use of these valuable but dangerous forms of therapy in an informed manner—as such, it should find a place on every doctor's desk.

E. J. ROSS

Modern Trends in Paediatrics—4

Edited John Apley, Bristol. 220 × 150 mm. Pp. 376+x. Illustrated. 1974. London: The Butterworth Group. £7·50.

THERE is a good deal in this book of value as well as of interest to any surgeon who has to deal with children. There are chapters on food and the fetus, growth of the fetus and the effects of drugs in fetal life and infancy, indicating how interest is steadily shifting to earlier stages of human development. The rapidly expanding field of antenatal diagnosis is also discussed and the present scope and future possibilities are assessed. There are other provocative and stimulating chapters on the treatment of acute lymphoblastic leukaemia, cystic fibrosis, the assessment of renal function, endocrinology, immunobiology and the emotional aspects of injury in children. Although it is becoming less common, hypertrophic pyloric stenosis remains an important problem for the surgeon and there is a good review of recent work, but the aetiology is still wrapped in mystery and confusion. There is also a discussion of learning, teaching and training in paediatrics and an excellent final chapter on ethical problems which should be read by everyone who has to treat children. This is a well-produced and easily read book and the editor is to be congratulated on the palatable and interesting mixture that he has achieved.

A. W. WILKINSON

Diseases of the Ear

Stuart R. Mawson, London. Third edition. 225×150 mm. Pp. 584+vii, with 286 illustrations. 1974. London: Edward Arnold. £18·50.

In this country all otologists are practising otorhinolaryngologists, although gradually there has been a tendency for a few particularly talented individuals to concentrate almost exclusively on this single facet of an increasingly expansive speciality. The author, as a member of this select fraternity, is therefore uniquely placed to write what has now become a standard textbook on the ear. The two previous editions were excellent and this, the third, is superb! It is obvious that the 7 years which have elapsed between editions has been spent by Mawson in an intensive reappraisal of his text together with a searching analysis of the new published material. These years have seen a dramatic change of emphasis in otology. The idol of technical expertise has been partially replaced by an awareness of the need for greater scientific understanding of the ear as a functioning unit. Unfortunately, owing to lack of financial support and interest, little of this work has emanated from this country. However, everything of practical importance is included in the third edition, making it not only ideal for the examination candidate but essential for all thoughtful otologists. The book remains compact both in page size and bulk—evidence of vigorous pruning and an understanding publisher. Since the text is all-embracing with nothing of importance left out, there is little purpose in reproducing a list of contents. The number of informative yet simple tables has been greatly increased and once again this is witness to the fact that the author is an experienced practical otologist with more than a passing interest in teaching. The section on operative surgery, which cannot offer adequate instruction to those who are really in need, may inadvertently make an intricate procedure appear deceptively simple!

The line drawings, as in previous editions, are the work of yet another otologist, and contribute more than is usual to the text. Even the clinical photographs, unfortunately in black and white, suffer less than is expected by the necessity for a drastic reduction in size for publication. There is little to criticize and much to admire. Whatever the price this book is worth the money, for, if nothing else, it indicates that with the right person, subject and publishers this country can still produce an outstanding medical book.

D. F. N. HARRISON

Surgical Treatment of Head and Neck Tumours

Edited Jorge Fairbanks Barbosa, São Paulo, Brazil. 280×215 mm. Pp. 311+xiii. Illustrated. 1974. New York: Grune & Stratton. £16.

This book is written by the senior staff of the head and neck service of the cancer centre of São Paulo, Brazil. The editor is a major contributor. One chapter on cancer of the middle ear is contributed by Professor Conley of New York, who also wrote the Foreword.

The contents constitute a testament of the current practice of the authors in the cancer centre in which they work. The work is not an attempt at an encyclopaedic statement of all surgical techniques available to the surgeon engaged in this field. The possible disadvantages of omission which this format entails are more than compensated by the authenticity of the writing by all the contributors. It is at once apparent to the reader that he is being given information clearly and in detail about methods in day-to-day use to meet varying clinical situations and which have been found to work. No omnipotence is claimed or implied, which is refreshing; one feels that one can disagree about detail here and there without offending.

The subject is very fully covered and the translation has been so well made that the spontaneity of the text has not been lost. The book is profusely illustrated with drawings of masterly clarity which greatly enhance its value to students of all levels of experience. The basic principles of radical excision and of reconstruction to meet functional and aesthetic requirements are repeatedly stated, together with sound common sense of the many needs, other than surgical, of patients so severely afflicted. Human understanding and surgical expertise are well blended.

The editor, in his preface, states that the naming of techniques after individual surgeons has been deliberately avoided for fear that an injustice might be done, but many names are mentioned in the text and it is a serious omission that no references are given at the end of any chapter. The index could also be enlarged for ease of reference by the reader, or more detail could be given beneath the chapter headings in the list of contents. The book is well produced, and it is a pity that an error in the binding of the reviewer's copy resulted in omission of half the index. It is possible that a list of references at the end of the book was also omitted by this error.

DAVID MATTHEWS

Current Pediatric Diagnosis and Treatment

Henry Kempe, Henry K. Silver, Donough O'Brien and associate authors. Third edition. 260×185 mm. Pp. 1020. Illustrated. 1974. Los Altos, California: Lange Medical Publications. $12.

This is the third edition of a well-known textbook. It aims to deal with principles of diagnosis and treatment in a way which will satisfy the requirements of the medical student and the paediatrician in the early stages of his training. It also tries to detail clinical methods and procedures in an implied attempt to be encyclopaedic. This is possibly the reason why, in spite of the immense amount of information which this book provides, one is left with rather a breathless feeling, but this may be unfair and unduly critical. It must be said that at a price of $12 a thousand pages seems good value, and the 51 authors cover a vast number of subjects. The opening chapters on history and physical examination are more a comprehensive catalogue than a discussion of how to go about obtaining a history and examining a baby, and perhaps this is right and a modern way to do it, but a bit more of fatherly advice might serve the student better.

A surgeon might be forgiven for feeling disappointed at the short shift given to both osteomyelitis and pyelonephritis in the newly born and even more so at the repetition of the advice to instil opaque medium into the upper pouch of the oesophagus to make the diagnosis of oesophageal atresia. In later sections the various causes of neonatal intestinal obstruction are described, but more cross references would be helpful, especially with the chapter on the neonate. Meconium plug obstruction is much more likely to be cleared by a Gastrografin than a barium enema. There are some diagrams and many tables some of which are very useful but more illustrations would be of value.

A. W. WILKINSON

Tumors of the Esophagus and Stomach

S-Chun Ming, Pennsylvania. 260×203 mm. Pp. 279. Illustrated. 1973. Washington: Armed Forces Institute of Pathology. No price given.

This book is a section of the *Atlas of Tumor Pathology* under the general editorship of Harlan I. Firminger and assisted by a very distinguished editorial advisory committee.

Every conceivable tumour of the oesophagus and stomach is described in great detail and the text is profusely illustrated; a number of the illustrations are in colour. For purposes of reference this book is invaluable and every care has been taken to give a proper sense of proportion to the rare conditions which are included. Perusal of the book, however, shows that this is much more than a book of reference. For example, the section on epidemiology and geographic incidence of cancer of the oesophagus gives a short but well-balanced account of the current views held on this aspect of the disease. Similarly, the controversial opinions regarding the relationship between chronic gastric ulcer and gastric carcinoma are summed up in a masterly way. The account of the conditions associated with cancer of the oesophagus is short but clear.

The contemporary bibliography is excellent but the interest of the reader could have been increased by the inclusion of the accounts of some of the earlier writers. This book should be read by all surgeons with a serious interest in tumours of the oesophagus and stomach and the author is to be congratulated on having made a major contribution to the subject.

R. H. FRANKLIN

Book notices

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and those having the greatest interest to our readers.]

International Awards for Biomedical Research and Research Training, National Institutes of Health, Fiscal Year 1973
Prepared by Internation Cooperation and Geographic Studies Branch, Fogarty International Center. 204 × 268 mm. Pp. 87+vi. 1974. Maryland: US Department of Health, Education and Welfare. No price given.

Cerebral Vascular Disease
Edited J. S. Meyer, H. Lechner, M. Reivich and O. Eichhorn. 230 × 155 mm. Pp. 280+xvi, with 108 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.42.

Face au cancer du sein. Actualités, 1973
Jacques Reynier et al. 210 × 270 mm. Pp. 132, with 141 illustrations. 1974. Paris: L'Expansion Scientifique Française. 83F.

Les Entretiens de Bichat 1974
Edited P. L. Chigot, A. Bellin and D. J. Duché. 224 × 174 mm. Pp. 495. 1974. Paris: L'Expansion Scientifique Française. 14.60F.

The Knee Joint. Recent Advances in Basic Research and Clinical Aspects
Edited by O. S. Ingwersen, Eindhoven, B. Van Linge, Rotterdam, Th. J. G. Van Rens, Nijmegen, G. E. Rosingh, Haarlem, B. E. E. M. J. Veraart, Arnhem, and D. Le Vay, Withyham, Sussex. 240 × 165 mm. Pp. 329+ix. Illustrated. 1974. Amsterdam: Excerpta Medica North-Holland. $30.80.

Rekonstruktive chirurgie der Arterien
Jorg Vollmar, Ulm. 260 × 175 mm. Pp. 451+xvi, with 353 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.184.

Les Fractures du Cotyle
Robert Judet and Emile LeTournel, Paris. 250 × 190 mm. Pp. 336, with 235 illustrations. 1974. Paris: Masson et Cie. 280F.

Les Complications Digestives du Stress

The Seward Identikit...

Every stainless steel Lloyd-Davies' Sigmoidoscope made by Seward has components which are absolutely identical – guaranteed interchangeable.

And that's an immense advantage when a lot of these instruments pass through the CSSD together. Because you never need to label any parts, or worry about 'matching up'.

Which saves time. Cuts losses.

You'll probably agree, the Seward Lloyd-Davies' Sigmoidoscope* is good news.

Well, here's some more.

The Seward St. Mark's Proctoscope*.

Made entirely of stainless steel. With all parts absolutely identical – guaranteed interchangeable.

**Electric and non-electric models available – leaflets on request*

seward –the fast word in quality

A. J. Seward, UAC House, Blackfriars Road, London SE1 9UG.

PRE-WAR TOY TRAINS

Wanted for local museum Bing, Hornby and Bassett-Lowke tinplate trains—clockwork, electric or steam, including any accessories however small. Condition is not important as often one piece can be used to restore another. We are aiming to set up as complete a collection of pre-war models as possible, and welcome any relevant items. Reasonable prices paid.

P. B. WHITEHOUSE J.P., Birmingham Railway Museum, 5 Birch Hollow, Edgbaston, Birmingham B15 2QE. *Tel.:* 021 454 7395.

Binding Cases

Binding cases for Volume 61 may be obtained from the Publishers at £1·25 post free. They are supplied in dark blue cloth with imitation gold lettering on the spine.

If desired, the publishers will undertake the binding at an inclusive charge of £4·00, post free.

JOHN WRIGHT

42–44 TRIANGLE WEST, BRISTOL BS8 1EX

New and Revised 11th Edition

Synopsis of Surgical Anatomy

Edited by D. J. du PLESSIS
CHM (Rand), FRCS (Eng)

Head of the Department of Surgery, University of Witwatersrand, Johannesburg; Chief Surgeon, Johannesburg General Hospital

A general revision has been undertaken to bring the whole book up to date and also to eliminate those sections which were not absolutely essential because it is important to prevent a book of this type from becoming too large. This new completely revised edition, with many excellent illustrations, is in two parts: Anatomy of the Normal and Anatomy of the Abnormal.

In preparation

About 928 pages 779 illustrations £7·00 net

New Surgical Titles from

CHURCHILL LIVINGSTONE

A TEXTBOOK OF SURGICAL PATHOLOGY

Sir **Charles Illingworth** and the late **Bruce M. Dick**

1975 Eleventh edition
376 pages illustrated £11·00

This volume of Surgical Pathology covers all aspects of the science of surgical diseases, including the relevant aspects of physiology and biochemistry as well as the traditional subjects of morbid anatomy and histology.

MAJOR AMPUTATIONS FOR VASCULAR DISEASE

J. M. Little

1975 128 pages illustrated £5·00

This book describes the specialised management of amputees who suffer from advanced vascular disease. There are technical descriptions of the amputations themselves and an analysis of the results that can be expected from them. The major feature is that the author adopts a 'whole patient' approach, with emphasis on the psychological adjustment to amputation.

THE INTERNAL AUDITORY MEATUS

Anatomy, Pathology and Surgery

M. Portmann, J. M. Sterkers, R. Charachon and **C. H. Chouard**

Translated by Anthony E. S. Richards

1975 318 pages illustrated £15·50

During the course of its existence as a speciality, otolaryngology has shown great capacity for change, and this has lead to the development of many new techniques which are discussed in this book.

Physical Examination of the Surgical Patient:

An Introduction to Clinical Surgery 4/e

By J. Engelbert Dunphy, M.D., Professor of Surgery, University of California School of Medicine, San Francisco, California, and Thomas W. Botsford, M.D., Associate Professor of Surgery, Harvard Medical School.

This fourth edition of **Physical Examination of the Surgical Patient** has undergone extensive revision, and introduces such new emphases as the problem orientated record and pathophysiologic mechanisms of surgical disease. Major changes to this edition appear in the elective examination of the breast, heart, abdomen, and the cancer patient; the emergency examination of the chest, abdomen, and the thermally injured patient. A more clear and concise listing of supplementary readings replaces the old bibliography, and many of the older figures have been replaced with new ones. A second colour plate of epidermal lesions has also been added.

430pp 215 illustrations (2 pages in colour) Cloth binding Price £8.85
Published March 1975

Surgery in the Aged

A title in the series Major Problems in Clinical Surgery

By Lazar J. Greenfield, M.D., Professor of Surgery, The University of Oklahoma Health Sciences Centre College of Medicine, Oklahoma City, Oklahoma.

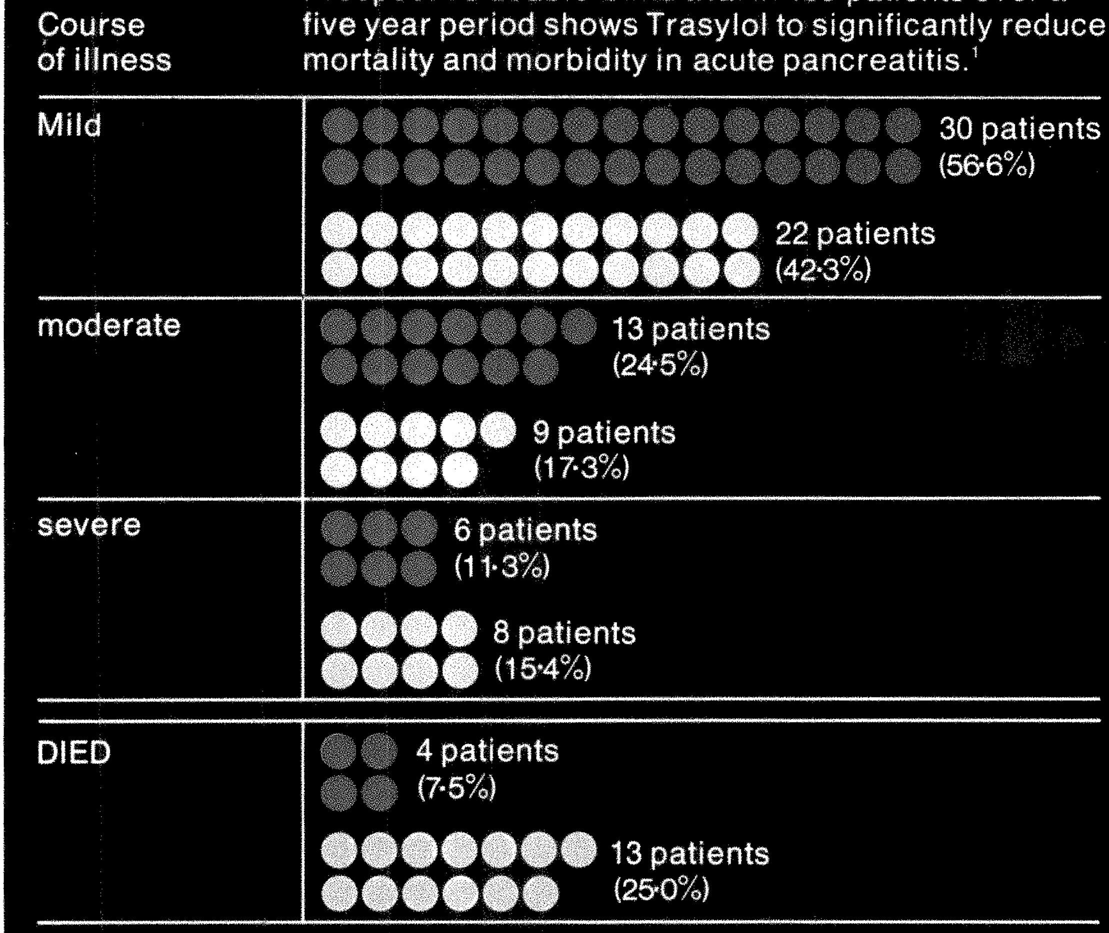
The new evidence for Trasylol in the treatment of acute pancreatitis

Prospective double-blind trial in 105 patients over a five year period shows Trasylol to significantly reduce mortality and morbidity in acute pancreatitis.[1]



● Trasylol group (53)

○ placebo group (52)

'Trasylol must therefore be regarded as a drug which is beneficial in the treatment of acute pancreatitis.'[1]

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 61. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

PRESENTATION OF STATISTICS

Authors are reminded that with the frequent use of statistical analysis in biological writing of all kinds it is desirable that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinical trials the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached.

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables,* 7th edition, 1970.

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

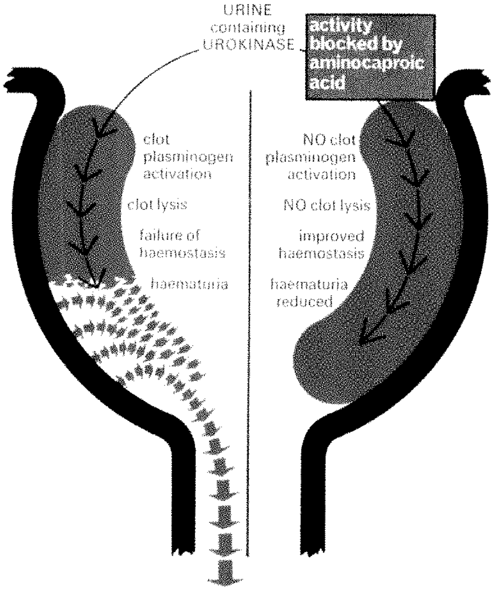
The
mechanism of
post-prostatectomy bleeding
and
EPSIKAPRON®
control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Bile salts and gallstone disease

COLIN MACKAY*

SUMMARY

Bile salts play an important role in maintaining cholesterol in aqueous solution in bile. There is evidence that in some patients at least gallstones arise as a result of bile salt deficiency. The evidence to date suggests that although oral bile salts may be of use in treating some gallstone patients they are unlikely to replace cholecystectomy in the foreseeable future. The instillation of bile salts via an indwelling T-tube may well be of great use in the management of stones retained in the common duct after choledocholithotomy. There is no doubt that in this branch of medicine as in all others prevention is better than cure and our aim should be to perfect our technique so that we do not leave stones behind. However, should the situation occur we may soon have safe effective physiological solvents to dissolve our mistakes.

GALLSTONE disease is a very common condition and there is evidence that it is becoming even commoner (Holland and Heaton, 1972). Although no accurate figures are available, probably about 10 per cent of the population of the United Kingdom aged over 40 years have gallstones most of which will be cholesterol in type (Sutor and Wooley, 1971). In this review three aspects will be considered: how bile salts maintain cholesterol in aqueous solution in bile, the part played by bile salts in the aetiology of gallstone disease and the role of bile salts in the treatment of gallstone disease.

Physiology

Bile salts are synthesized in the liver from cholesterol (Bergstrom and Danielsson, 1968; Mosbach, 1972), and indeed they constitute the major pathway of cholesterol excretion by the body. In man there are two primary bile acids, cholic and chenodeoxycholic, and these are excreted in bile conjugated with glycine or taurine. After entering the small bowel they pass along its length before being actively reabsorbed in the terminal ileum. This is normally a most efficient process such that some 95 per cent of bile salts are reabsorbed to return via the portal circulation to the liver and be re-excreted in bile. The bile salts in the enterohepatic circulation constitute the bile salt pool, which in man amounts to 2–4 g and recirculates two or three times during the digestion of a single meal. A small percentage of bile salts pass through the terminal ileum into the colon where they encounter bacterial enzymes. These enzymes produce deconjugation and dehydroxylation such that the glycine and taurine moieties are split off and cholate is dehydroxylated to deoxycholate and chenodeoxycholate to lithocholate. Deoxycholate is reabsorbed and returns in the portal circulation to the liver where it is conjugated with glycine or taurine and excreted in bile as a secondary bile salt. Lithocholate, on the other hand, is insoluble and is excreted in the stool so that in man only trace amounts are present in bile. Thus in human bile there are normally glycine and taurine conjugates of cholic, chenodeoxycholic and deoxycholic acids.

The principal lipids in bile in addition to the bile salts are cholesterol and phospholipid which is almost entirely lecithin. Each of these three substances is amphiphilic, i.e. part of the molecule is soluble in water and part is soluble in fat solvents. The taurine and glycine moieties of bile salts, together with the hydroxyl groups, are so strongly water soluble that they bring the whole molecule into aqueous solution and so bile salts are water soluble. However, this is not so with lecithin and cholesterol. The water soluble portions of these molecules are relatively so small that they are not strong enough to bring the rest of the molecule into aqueous solution and so lecithin and cholesterol are not soluble in water. The principal function of bile salts in bile is to maintain in aqueous solution these two substances, lecithin and cholesterol. A description of the physicochemical processes involved is beyond the scope of this article but the subject has been well reviewed by Carey and Small (1970); suffice it to say that this process of solubilization is brought about by the formation of mixed micelles—structures with a water soluble coating and a water insoluble core. In bile the bile salts form the water soluble coating and lecithin and cholesterol the water insoluble core. Lecithin, although itself insoluble in water, plays an important role in enhancing the solubility of cholesterol in bile salt micelles. Bile salt micelles are able to dissolve relatively small amounts of cholesterol, but in the presence of lecithin

the micelle is expanded and the cholesterol solubility enhanced.

In the small intestine bile salts play an important role in the digestion and absorption of fat. They aid in the emulsification of fat, help activate pancreatic lipase and render water soluble the products of pancreatic lipolysis. Pancreatic lipase hydrolyses triglyceride into monoglyceride and fatty acid, substances which are insoluble in water but which are rendered water soluble by the formation of mixed micelles with bile salts. Bile salts are similarly involved in the absorption of the fat soluble vitamins.

Bile salts and aetiology of gallstones

We have established the role of bile salts in maintaining cholesterol in aqueous solution in bile. This process was further elucidated by Admirand and Small (1968), who constructed an *in vitro* model system which allowed the prediction of the maximum amount of cholesterol which could be dissolved in aqueous solutions containing varying proportions of bile salt and lecithin. They expressed their results on triangular coordinates and constructed a phase diagram as shown in *Fig*. 1. All mixtures whose relative composition lay within the shaded area were in micellar solution whereas all others contained crystals of cholesterol. They then studied the relative amounts of bile salt, cholesterol and phospholipid in gallbladder bile from patients with cholesterol gallstones and in bile from patients without gallstones. They showed that normal bile was less than saturated with cholesterol relative to bile salt and phospholipid whereas bile from patients with cholesterol gallstones was saturated and in some cases contained insoluble cholesterol in the form of microcrystals. As a result of these studies they suggested that the physical state of bile (i.e. the presence or absence of insoluble cholesterol) was determined by the relative concentration of bile salt, lecithin and cholesterol.

There is no doubt that this was a major advance in the understanding of the aetiology of gallstones, but it is important to emphasize that they established the limits of cholesterol solubility from *in vitro* studies and that only one bile salt, sodium taurocholate, was studied. Whether or not their findings apply *in vivo* and are applicable for all bile salts remains to be shown and this should be borne in mind when their findings are applied to the clinical situation. They themselves showed that alteration of the total solids outwith the range of 5–20 per cent altered the line of maximum solubility of cholesterol in bile salt and lecithin, and it may well be that other factors, as yet unknown, also alter the limits of solubility. With these reservations, however, it would appear, from the studies of Admirand and Small, that cholesterol gallstones are associated with gallbladder bile which is saturated with cholesterol.

Is this bile secreted in a saturated form by the liver or does it become saturated in the gallbladder? Almost simultaneously Small and Rapo (1970) and Vlahcevic et al. (1970b) reported studies in which they examined the relative composition of gallbladder bile and hepatic bile in patients undergoing cholecystectomy for cholesterol gallstones. Both groups showed that hepatic bile was supersaturated with cholesterol and the conclusion was reached that cholesterol gallstones were due to the production by the liver, and not the gallbladder, of abnormal bile. Since these two studies were reported, others studying the relative composition of bile at the time of cholecystectomy have shown that while many patients with cholesterol gallstones secrete supersaturated hepatic bile this is not always the case, as shown by MacKay et al. (1972), Smallwood et al. (1972) and Heller and Bouchier (1973). The latest data of the author are shown in *Fig*. 2, from which it is evident that although many patients with cholesterol gallstones do secrete hepatic bile which is supersaturated with cholesterol, a large number secrete bile whose relative composition lies within the micellar zone. Studies of bile composition in gallstone patients are open to the criticism that they give no indication of the composition of bile pertaining at the time of initiation of stone formation, and it is entirely possible that patients with a bile which is not supersaturated at the time of cholecystectomy could well have secreted supersaturated bile at some time in the past. The finding of undersaturated bile at the time of cholecystectomy does not therefore preclude the part played by supersaturation of bile in the initiation of gallstone formation.

Supersaturated bile came to be known as 'lithogenic', but care should be exercised in the use of this term. Nakayama and Van der Linden (1970) showed that many patients without gallstones secreted supersaturated bile, and Metzger et al. (1973) showed that fasting bile was consistently more 'lithogenic' than gallbladder bile or hepatic bile obtained during feeding and this occurred even in patients without gallstones. Metzger's findings were supported by Northfield and Hofmann (1973), who showed that the secretion of 'lithogenic' bile occurred with equal frequency in gallstone patients and controls, especially during overnight fasting, and seemed to be physiological. It may be that the production of supersaturated bile during fasting, if prolonged or combined with inadequate mixing within the gallbladder, could be an important factor in the formation of cholesterol gallstones.

The association of cholesterol gallstones with supersaturation of bile gains support from some epidemiological and animal studies. Redinger and Small (1972) have collected data showing that there is a correlation between the prevalence of gallstone disease and the degree of saturation of gallbladder bile in different ethnic groups. From *Fig.* 3 it is evident that young North American Indian females who have a high prevalence of cholesterol gallstones also have a high percentage of cholesterol saturation in bile, whereas the African Masai, a population in which cholesterol gallstones do not occur, have a much lower percentage saturation. These workers also cited data from animal studies showing that animals which do not form gallstones spontaneously and only with difficulty by dietary manipulation, e.g. dog and pig, secrete bile containing little cholesterol relative to bile salt and phospholipid. Hamsters, on the other hand, secrete bile with a relatively higher proportion of cholesterol and although they do not form stones spontaneously they can be induced to do so fairly readily by dietary manipulation. Baboons secrete bile which has a relative composition approaching the limits of cholesterol solubility and they are known to form stones spontaneously without dietary manipulation. These data are illustrated in *Fig.* 4.

How can the current state of knowledge be summarized? It would appear that in many patients with cholesterol gallstones hepatic bile contains an excess of cholesterol relative to bile salt and phospholipid, and even in the others the bile may well have been supersaturated at some time in the past. In view of the fact that bile is 'normally' supersaturated when patients are fasting it is perhaps not surprising that some patients develop gallstones but more surprising that all patients do not develop a stone. It should be emphasized that supersaturation is only one event in the formation of a gallstone; it has to be followed by the precipitation of cholesterol and the formation of microstones which enlarge to form macrostones (Small, 1970). It may well be that in patients who do not develop gallstones precipitation does not occur or should it occur the crystals are washed out in the bile into the gastro-intestinal tract.

We have established the role of supersaturation of hepatic bile in the aetiology of cholesterol gallstones.

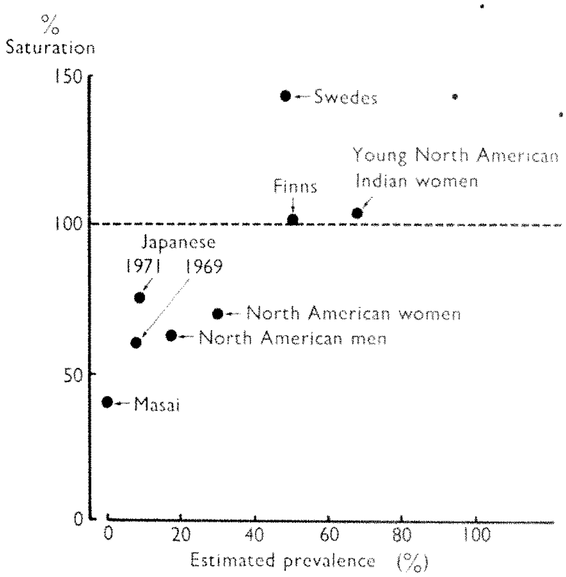

Fig. 3. Percentage cholesterol saturation of gallbladder bile in different populations (from the data of Redinger and Small, 1972, as adapted by Lukie and Dietschy, 1973).

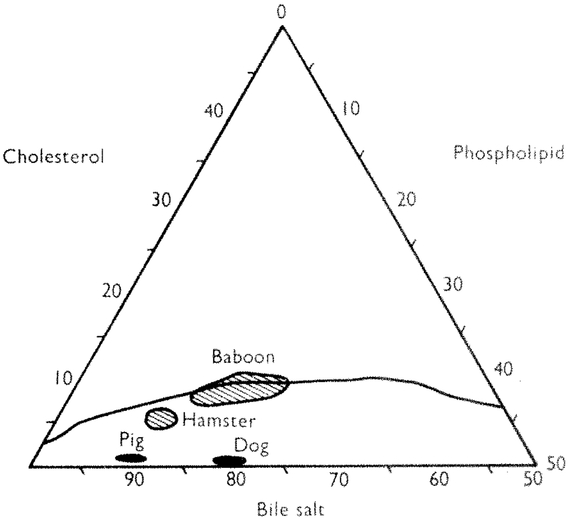

Fig. 4. Relative composition of animal gallbladder bile (adapted from Redinger and Small, 1972).

Theoretically, this could arise from excessive cholesterol secretion or impaired bile salt and/or phospholipid secretion. There is some evidence to suggest that cholesterol intake may influence bile composition but little evidence to incriminate phospholipid. These subjects are beyond the scope of this article which considers the evidence that cholesterol gallstones are due to a lack of bile salts. It is possible to measure the size of the bile salt pool in man by administering bile salt labelled with a radioactive isotope and aspirating specimens of bile by duodenal intubation. Vlahcevic et al. (1970a) measured the pool size by this method of isotope dilution; they gave ^{14}C cholic acid to gallstone patients and controls and found that the pool size was significantly smaller in the gallstone patients. Arnesjö and Stahl (1973) and Danzinger et al. (1973) also reported a reduced bile acid pool size in gallstone patients. However, it could be argued that the diminished pool size was the result rather than the cause of the gallstones. The studies of Bell et al. (1973) would suggest that the diminished pool size was more likely to precede than to result from the gallstones. They studied bile salt pool size in three groups of American Indians, namely: (*a*) patients with gallstones and saturated bile; (*b*) patients without gallstones but saturated bile; (*c*) patients with no gallstones and normal bile. The pool size was greatly diminished in both groups of saturated bile patients. The fact that the pool was reduced even in the patients with no evidence of gallstones would suggest that the reduced pool preceded rather than resulted from the gallstones. Care must be taken in drawing too many conclusions from studies in American Indians with their remarkably high prevalence of gallstone disease (Sampliner et al., 1970), as the aetiology in such patients may be very different from the aetiology in other populations with a much lower prevalence of gallstone disease.

The hypothesis that a diminished bile acid pool size is responsible for the production of cholesterol gallstones received further support from the work of Heaton and Read (1969). They studied the prevalence of gallstones in patients who had previously undergone resection of the terminal ileum, the bile-salt-absorbing area of the gut, and found the prevalence to be significantly higher than in control groups. Abaurre et al. (1969) have shown that patients with ileal resection have a diminished bile salt pool.

It has been assumed that this small bile acid pool recirculates at the normal rate in the enterohepatic circulation, thus leading to a reduced secretion rate of bile acid but not cholesterol in bile. Northfield and Hofmann (1973) studied biliary lipid output in patients with radiolucent gallstones and in matched controls. They found that there was an inverse relationship between the size and the recycling rate of the bile salt pool so that the bile salt secretion rate remained constant over a wide range of pool sizes. They found that the total daily output of all three biliary lipids was similar in gallstone patients and controls. This is in contrast to the findings of Grundy et al. (1972), who showed that obese American Indian women with gallstones had a higher cholesterol output and a lower bile salt output than thin Caucasian controls, the diminished bile salt output probably arising from impaired hepatic synthesis. This difference may well be racial, the American Indians having a much higher prevalence of gallstone disease. Low-Beer and Pomare (1973) also showed that the size of the bile salt pool was largely determined by the frequency of its enterohepatic circulation. Therefore the exact role of a small bile acid pool in the pathogenesis of cholesterol gallstones remains to be determined.

The part played by a reduced bile salt pool in the production of cholesterol gallstones has been considered, but is there any evidence that an alteration in its component bile salts is responsible for gallstone formation? Van der Linden (1971) has reviewed the available literature and shown that there is a tendency for patients with gallstones to have an increase in dihydroxy bile salts relative to trihydroxy salts. He pointed out that while the difference did not reach the level of statistical significance in many of the studies reported the regular trend could not be ignored. The ratio of trihydroxy to dihydroxy bile salts in gallstone and duodenal ulcer patients studied by the author was found to be 0·44 and 0·67 respectively, the difference being statistically significant. Similar findings have been reported by Arnesjö and Stahl (1973) and Heller and Bouchier (1973). There would seem, therefore, to be good evidence that gallstones are associated with a relative increase in dihydroxy or a relative decrease in trihydroxy bile salts. Dihydroxy bile acids have been claimed to form larger micelles with less surface charge and consequently less stability (Bouchier and Freston, 1968), and a shift towards these acids may therefore favour gallstone formation. Haslewood (1967) has suggested that man's liability to gallstones may be connected with the fact that while having a herbivore's bile acid pattern, i.e. mainly dihydroxycholanic acids, he eats to a great extent a carvinore's diet and carnivores have predominantly cholic acid. The ratio of glycine-conjugated to taurine-conjugated bile salts in gallstone and duodenal ulcer patients studied by the author was found to be 2·4 and 2·1 respectively, the difference not reaching a level of statistical significance. Similar findings were reported by Arnesjö and Stahl (1973). Alterations in the patterns of conjugation cannot therefore be incriminated.

A few years ago it seemed as if the gallstone problem had been solved, the cause being a hepatic abnormality resulting in the production of bile supersaturated with cholesterol. Since then further data have complicated rather than simplified the problem, and recently the gallbladder has again been implicated. In the past stasis and infection in the gallbladder were blamed with little good scientific evidence. Dilatation of the gallbladder occurs in the later stages of pregnancy (Gerdes and Boyden, 1938), in the progesterone phase of the menstrual cycle (Nilsson and Stattin, 1967) and after truncal vagotomy (Rudick and Hutchison, 1964; Parkin et al., 1973). Gallstones are commoner in females than in males, certainly in the childbearing age groups, and may be commoner in patients after vagotomy, although this is a matter for debate (Fletcher and Clark, 1968). Impaired gallbladder emptying with stasis of bile and particularly bile salts may lead to a functional diversion of bile salts from the enterohepatic circulation and a tendency, therefore, for hepatic bile to become temporarily supersaturated, with the risk of cholesterol precipitation. The whole question of the role of the gallbladder in the aetiology of gallstones requires further investigation, especially since it has been shown that hepatic bile which was supersaturated prior to cholecystectomy tends to become normal after removal of the gallbladder (Shaffer et al., 1972; Simmons et al., 1972; Smith et al., 1973).

Bile salts and the treatment of gallstone disease

Thistle and Schoenfield (1971) at the Mayo Clinic were the first to show that the oral adminstration of chenodeoxycholic acid to women with gallstones produced a significant increase in the ratio of cholesterol-solubilizing agents in bile to cholesterol, i.e. the 'lithogenic' potential of bile was decreased. This group then went on to show (Danzinger et al., 1972) that chenodeoxycholic acid not only improved the relative composition of bile by expanding the diminished bile salt pool but caused stones to decrease in size and even disappear in some patients. These results were confirmed in this country by Bell, Whitney and Dowling (1972). The next step was to establish a trial, and the initial results of a single blind controlled therapeutic trial have been reported from the Mayo Clinic by Thistle and Hofmann (1973). They studied 53 patients with asymptomatic radiolucent gallstones in functioning gallbladders. The patients received chenodeoxycholic acid, cholic acid or a placebo. After 6 months 11 of 18 patients receiving chenodeoxycholic acid showed a decrease in gallstone size or number, but no response was observed in the 17 treated with cholic acid or in the 18 receiving a placebo. Since then a multicentre investigation into the efficacy and safety of chenodeoxycholic acid has been initiated in the United States of America supported by the National Institutes of Health (Schoenfield, 1974).

There is therefore no doubt that chenodeoxycholic acid is effective in treating some patients with gallstones but many questions remain to be answered:

1. What is the optimum dose?
2. What are the side effects of treatment?
3. Is long term treatment safe?
4. Why is chenodeoxycholic acid effective and cholic acid ineffective?
5. Is chenodeoxycholic acid the best bile acid?
6. Has treatment to continue for life?
7. Does the calcium content of the stone affect its rate of dissolution?
8. What are the contraindications to treatment?

1. *Dosage*

The dosage of chenodeoxycholic acid used in the early studies ranged from 1·5 to 4·5 g/day but this has been reduced in later studies. In the Mayo Clinic trial the dose varied from 10 to 26 mg/kg body weight. The lowest therapeutic dose remains to be determined.

2. *Side effects*

One of the potentially most troublesome side effects is diarrhoea due to the secretion of water and electrolytes by the colonic mucosa. This is dose related, and in the controlled trial reported by Thistle and Hofmann (1973) patients adjusted the dose so that the stools were usually partially or completely formed. Symptoms of gastric irritation have not occurred to any great extent in the studies reported.

3. *Safety of long term treatment*

The main worries over long term treatment are liver damage and the development of atheroma. Chenodeoxycholic acid may induce liver damage directly or via its bacterial metabolite lithocholic acid. Transient elevation of the serum transaminases during treatment has been reported (Thistle and Hofmann, 1973). Bell et al. (1974) studied liver biopsies from patients receiving chenodeoxycholic acid (0·5–1·5 g/day) and from patients with untreated cholelithiasis and found no appreciable difference; they considered that in this dosage chenodeoxycholic acid was not hepatotoxic.

There are several reasons, albeit theoretical, why the long term administration of bile salt might lead to cholesterol retention by the body and the risk of atheroma. First, the administration of exogenous bile salt will inhibit endogenous bile salt synthesis, thus abolishing one of the major excretory routes for cholesterol. Secondly, exogenous bile salt may well enhance the intestinal absorption of dietary and endogenous cholesterol. Thirdly, since bile salts alter the relative composition of bile in such a way that there is a smaller percentage of cholesterol, unless a marked increase in bile secretion occurred the total secretion of cholesterol into the intestine would be depressed (Small, 1971). These theoretical considerations were put to the test by Hoffman et al. (1974). They measured the cholesterol pool and the cholesterol input to the pool in 23 patients with gallstones; 8 receiving chenodeoxycholic acid, 7 receiving cholic acid and 8 receiving a placebo. The values were similar in all three groups and were almost the same as those reported for patients without gallstones. They concluded that chenodeoxycholic acid did not cause any major change in the body's cholesterol metabolism and that the likelihood of detectable acceleration of atheroma was quite small. They admitted, however, that any increase in cholesterol pool size may have been too small to be detectable by presently available methods. In addition, bile salts were given for a period of 6 months and the effect of more prolonged administration is unknown. It may well be that patients with hyperlipidaemia, atheroma or a tendency to develop atheroma behave in a different way; these patients may have difficulty in excreting cholesterol and the additional strain imposed by bile salt adminstration may further exacerbate cholesterol handling. Further work is required before chenodeoxycholic acid can be completely cleared of the charge of being potentially atherogenic.

4. *Mechanism of action*

The precise mechanism by which chenodeoxycholic acid alters the composition of bile and produces gallstone dissolution is not clear. It cannot simply be due to an increase in the size of the bile salt pool because cholic acid also increases the bile salt pool size and yet does not alter the relative composition of bile or dissolve gallstones. Recent measurements of biliary lipid secretion before and after ingestion of chenodeoxycholic acid suggest that its major effect is to cause a relative or absolute reduction in cholesterol secretion (Northfield et al., 1973). Salen et al. (1973) have reported data suggesting that chenodeoxycholic acid reduced the activity of HMG-CoA reductase, an enzyme which regulates cholesterol synthesis by the liver. Confirmation of these findings is awaited.

5. *Best bile acid*

To date chenodeoxycholic acid is the best available. Farrell et al. (1973) have shown by *in vitro* studies of gallstone dissolution that dihydroxy bile salts are more efficient than trihydroxy bile salts and glycine conjugates more efficient than taurine conjugates. It may well be that further work will produce a more effective bile salt or even a better synthetic detergent.

6. *Length of treatment*

The natural history of patients whose gallstones have been dissolved medically is unknown, but it would seem that the relative composition of bile returns to pre-treatment values within 1 month of stopping treatment. Gallstones recurred in 2 of the first 5 patients in whom therapy was discontinued for 1 year. It may well be that even after successful stone dissolution continuous or intermittent prophylactic therapy will be necessary (Schoenfield, 1974).

7. *Effect of calcium content of stone*

Bell, Sutor et al. (1972) showed from *in vitro* studies that an outer ring of calcification delayed gallstone dissolution. In Thistle and Hofmann's (1973) trial of 13 patients with radio-opaque gallstones, 11 showed no change in stone size or number in response to chenodeoxycholic acid, presumably because the calcium prevented the bile salt from gaining access to the cholesterol.

8. *Contraindications*

There would seem to be no point in treating patients with blockage of the cystic duct as the bile salt would not enter the gallbladder to dissolve the stones. Similarly, treatment is contraindicated in patients with a high calcium content of the stones, as bile salt, although entering the gallbladder, would be unable to dissolve the stones. However, it remains to be shown how accurate an estimate of stone calcium can be made from inspection of a radiograph.

The safety of treatment in pregnancy and inflammatory bowel disease is quite unknown.

How can we summarize the current position of chenodeoxycholic acid in the treatment of cholesterol gallstones? There is no doubt that stones can be dissolved, but the place of this therapy in the management of the condition as a whole requires much more investigation and should at the moment be considered to be at the research and development stage. The words of Kurt Isselbacher (1972) are still true: 'In the meantime our surgical colleagues can relax, their treatment of gallstones, although threatened, is not yet out-moded.'

Does this mean that bile salts have no place in the surgeon's armamentarium? There may well be an important use for bile salts in the management of the stone retained in the common bile duct following choledocholithotomy. While no surgeon will admit to seeing this condition frequently, it is surprising how often such cases are referred from that mythical 'other hospital'. These patients are often frail and poor surgical risks and the retained stone is frequently small, otherwise it would not have been missed in the first place. Most of us have at some time or another spent time and sweat looking for a stone which was blatantly obvious in the T-tube cholangiogram but not nearly so obvious at the second operation. For these reasons it would be useful to have a safe effective gallstone solvent which could be introduced via the indwelling T-tube. Do bile salts come into this category?

Way et al. (1972) reported results from 22 patients with residual stones in the common bile duct who had a sodium cholate solution infused via an indwelling T-tube. Stones were eliminated in 12 patients while the treatment was unsuccessful in the remaining 10. Lansford et al. (1974) reported success in 5 of 6 patients treated in a similar fashion. The solution is sterilized by Millipore filtration and is given by gravity drip in such a way that excessive pressure rises within the common duct are avoided. Diarrhoea almost always arises owing to the cathartic action of the bile salt, but this can usually be controlled with cholestyramine.

Although preliminary experience with this method of treatment is promising it must be stated that it has not been subjected to a controlled trial. In addition, postoperative cholangiograms can be difficult to interpret and all filling defects are not stones. For this reason more than one cholangiogram should be performed before using bile salt infusion. It is difficult to be sure how sodium cholate exerts its beneficial effect—how much is due to cholesterol solubilization and how much to mechanical flushing. Catt et al. (1974) have shown that simply infusing saline was successful in 6 out of 10 patients. Farrell et al. (1973) have found from *in vitro* studies that trihydroxy bile salts such as sodium cholate are less effective than dihydroxy bile salts at dissolving gallstones. However, it may be unnecessary to dissolve the stone completely; simply reducing it to a size at which it starts to disintegrate or is small enough to negotiate the ampulla of Vater may be sufficient.

Gardner (1973) has reported stone disappearance following the infusion of heparinized saline, and the combined use of heparin and bile salts merits further investigation.

Orthotopic liver transplantation: an experimental study on the prevention of infections with Gram-negative organisms

S. W. SCHALM, D. T. POPESCU, D. VAN DER WAAY, R. A. F. KROM, W. D. H. HENDRIKS, J. L. TERPSTRA AND C. JERUSALEM*

SUMMARY

Infection with Gram-negative bacteria is frequently the cause of death in human liver transplantation. In experimental liver transplantation in mongrel dogs we detected Gram-negative septicaemia in 73 per cent of our first 15 cases; maximal survival was 26 days.

In a second series of 27 orthotopic liver transplantations in tissue-typed littermate dogs and littermate pigs the standard surgical technique and aftercare were changed with regard to four factors: an end-to-end common bile duct anastomosis was made instead of a gallbladder to duodenum anastomosis; the continuous postoperative bacteriostatic antibiotic therapy was changed to a single 2-day course of bactericidal antibiotics; preoperative selective bowel decontamination combined with postoperative protective isolation was introduced; the dosage of azathioprine used for immunosuppression was reduced.

Infectious complications decreased markedly to 8 per cent, with survival beyond 1 year in 37 per cent of the animals. Therefore under experimental conditions Gram-negative septicaemia can be prevented in liver transplantation; whether all the factors cited above are important in this regard remains to be determined.

INFECTION with Gram-negative organisms is common after liver transplantation and frequently is a major cause of death (Fulginiti et al., 1968; Starzl, 1969; Murray-Lyon et al., 1970; Williams et al., 1973). In our laboratory death due to sepsis with Gram-negative micro-organisms (liver abscesses and cholangitis) occurred in 73 per cent of mongrel dogs with a liver transplant in spite of continuous systemic antibiotic treatment as advocated by Brettschneider et al. (1968). This incidence of lethal infectious complications contrasts with the results of Brettschneider et al., who reported long term survival in 6 out of 12 dogs when intensive immunosuppression was combined with continuous antibiotic treatment.

This report concerns an experimental study designed to reduce infections with Gram-negative bacteria in animals with a liver transplant. Our standard surgical technique and aftercare, which closely resembled that of Brettschneider et al. (1968), was changed as follows: a common bile duct to common bile duct anastomosis was performed instead of a gallbladder to duodenum anastomosis; intensive preoperative selective bowel decontamination and postoperative protective isolation for 1 month were introduced; bactericidal antibiotics (ampicillin/gentamycin) only on the day of surgery and the next day replaced the continuous antibiotic regimen with the bacteriostatic chloramphenicol; the azathioprine dose was lowered from 4 mg to 1–2 mg/kg day^{-1}, as tissue-typed littermate dogs and littermate pigs were used as experimental animals.

The marked decrease in infectious complications obtained in this series of experiments appears to justify publication of our findings. It should stimulate controlled investigations on how human liver transplant recipients should be managed to prevent lethal Gram-negative sepsis.

Materials and methods

Experimental groups (Table I)

Group I comprises 15 mongrel dogs with survival beyond 5 days in which surgical technique and aftercare were almost identical to those of Brettschneider et al. (1968) with the exception that (*a*) neomycin was administered preoperatively (2 × 1 g on day − 1) and postoperatively (2 × 250 mg for 14 days), and (*b*) antilymphocyte globulin treatment was not given. Biliary drainage was accomplished by gallbladder to duodenum anastomosis. Azathioprine (Imuran) was administered postoperatively in a dosage of about 4 mg/kg day^{-1} orally. Chloramphenicol 250 mg twice daily was given intravenously during surgery and thereafter orally.

Groups II and III encompass 15 littermate dog pairs with identical lymphocyte typing (Vriesendorp et al., 1971) and 12 littermate pig pairs respectively. The details of anaesthesia, metabolic care (Popescu, 1973) and the surgical technique are described elsewhere (Krom, 1975). Relevant details concerning animal care, the type of biliary drainage and antibiotic and immunosuppressive treatment are given below.

The dogs in group II received 3 × 5 g neomycin and 3 × 5 g streptomycin orally on the day before the operation. Biliary drainage was by end-to-end common duct anastomosis over an internal splint (*Fig.* 1). Postoperative azathioprine treatment was

Table I: SUMMARY OF THE TREATMENT OF THE THREE GROUPS

Group	No. of experiments	Species	Bile duct anastomosis	Antibiotics: Non-resorbable	Antibiotics: Systemic	Azathioprine dose	Protective isolation
I	15	Dogs, mongrel	GB-D	Neomycin 3 g	Chloramphenicol	4–5 mg/kg	No
II	15	Dogs, littermates, tissue-typed	CBD-CBD, internal splint	Neomycin 15 g, streptomycin 15 g	Ampicillin, gentamicin	2–2·5 mg/kg	Yes
III	12	Pigs, littermates	CBD-CBD, spatulation, no splint	Neomycin 15 g, kanamycin 15 g	Ampicillin, gentamicin	1 mg/kg	Yes

GB-D, Gallbladder to duodenum anastomosis.
CBD-CBD, End-to-end common bile duct anastomosis.

2 mg/kg day^{-1} per os. Ampicillin (2 × 30–50 mg) and gentamicin (2 × 2–3 mg/kg day^{-1}) were given intramuscularly only on day 0 and day 1. On the day before the operation the animal was placed in a room where protective isolation was maintained. Fresh air from outside was blown into the room, creating a pressure gradient over the entry to the room. Operating theatre shoes, gowns and gloves were worn by those entering the room. Tosylchloramine 2 per cent was used for disinfection and cleaning. Postoperatively, the animal received fresh tap water twice daily and sterile food pellets (Hope Farms) which had been autoclaved at 1 atmosphere for 10 minutes. Protective isolation was maintained for at least 1 month.

The pigs in group III received 3 × 5 g neomycin and 3 × 5 g kanamycin orally on the day before transplantation. Biliary drainage was by end-to-end common duct anastomosis with a lumen-widening technique (spatulation); no splint was used (*Fig.* 1). Systemic antibiotics and protective isolation were as in group II. In 4 animals postoperative protective isolation was limited to 1 week. The dose of azathioprine was 1 mg/kg day^{-1}. The data for all the groups are summarized in *Table I*.

Bacterial studies

All material for culture (except the faeces) was placed in trypticase soy broth bottles at 37 °C and observed for at least 7 days for aerobic and anaerobic growth. In group I bacterial studies were not performed systematically. In groups II and III the following investigations were done routinely in all the animals; however, satisfactory material for bacteriological investigations was not always obtained.

1. Samples of the liver and the donor's and recipient's common bile duct were taken for culture at surgery.
2. Blood cultures were taken on days 2 and 5 and thereafter when clinically indicated. Blood was obtained by puncture of a peripheral or jugular vein after washing and disinfecting the skin with 2 per cent iodine in 70 per cent alcohol.
3. Liver biopsies were attempted on day 5 and when clinically indicated. Half of the biopsy material was cultured. The liver biopsies were obtained by the percutaneous Menghini-needle technique after skin preparation as in 2.
4. Faeces were collected within 2 hours after excretion. The faecal sample was placed in a small plastic tube and frozen in liquid nitrogen. The antibiotic sensitivity of the faecal flora in a preoperative specimen was tested according to the method of van der Waay et al. (1970); in the postoperative specimens the total number of bacterial colonies belonging to the family Enterobacteriaceae was determined per gramme of faeces.
5. Complete autopsies were performed on all the animals in groups I, II and III. Macroscopic evidence of infection was defined as the finding of an abscess. Tissue samples of liver, gallbladder and sometimes other organs were taken for histological examination. On microscopic examination infection was assumed to be present when bacteria or abscesses were seen in tissue sections. For groups II and III an attempt was made to perform the autopsy within 2 hours after death; under aseptic conditions material for culture was obtained from the liver, and the heart was punctured for blood.

Results

Survival

In group I mean survival was 11 days with a range of 3–26 days, while in groups II and III mean survival amounted to 32 days* with 10 animals (37 per cent) surviving for 1 year. Except for one, all the animals surviving for 2 months lived longer than 1 year.

Incidence of bacterial infections (*Table II*)

Eleven of the 15 dogs of group I showed macroscopic or microscopic evidence of infection at autopsy. In the cases where positive cultures were obtained, either while alive or at autopsy. Gram-negative bacteria were found consistently. In the great majority of cases the infection was considered to be the major cause of death. In contrast, although cultures of the liver or common duct were positive at surgery in about 40 per cent of cases, definite evidence of postoperative infection was found in only 2 of the 27 animals of groups II and III; in only 1 animal was infection considered to be a major cause of death. The postoperative course of this animal was complicated by hematemesis on day 7; emergency vagotomy and pyloroplasty were carried out. The liver biopsy taken at the completion of surgery was positive for *Escherichia coli*. Three weeks later persistent bacteraemia (*E. coli*) developed. Response to chloramphenicol was excellent. Three months later the animal died during a rejection episode; a large subphrenic abscess was found in addition to histologically confirmed rejection. In the other animal with definite infection *Candida albicans* was found in the liver biopsy taken on day 14 and in the gallbladder at autopsy (culture and histology); the infection, however, was not considered of clinical importance.

No definite infections were diagnosed in any of the other 25 animals in groups II and III. However, *E. coli* was found in both liver and blood cultures in 4 animals at autopsy; 1 animal was found dead as a result of a necrotic small bowel volvulus 3 days after transplantation, while the other 3 animals died of hepatic failure (bilirubin > 10 mg per cent and the prothrombin time was prolonged more than three times) caused by rejection. Macroscopic or microscopic evidence of infection was not found at autopsy and blood cultures taken the day before death in 2 animals remained negative.

Response to attempted selective bowel decontamination differed in dogs and pigs (*Fig.* 2). All the dogs showed bloodstained diarrhoea on day 0. Enterobacteriaceae species were virtually absent in the faeces for about 2 days; after a week recolonization was almost completed. The response in pigs was much poorer. No diarrhoea was noticed in any of the animals; in only 3 of the 9 animals tested was a colony count of 10 Enterobacteriaceae species or less obtained. Retrospectively, sensitivity testing revealed that only 5 of the 9 animals were sensitive to the antibiotics given (neomycin/kanamycin); a combination of cephaloridine/neomycin showed excellent *in vitro* growth inhibition in nearly all the animals.

Discussion

Several important conclusions can be drawn from this prospective, albeit uncontrolled, study. In about 40 per cent of the cases Gram-negative bacteria were cultured from liver or bile duct samples taken during the operation. This emphasizes the necessity of antibiotic treatment in experimental liver transplantation. The adequacy of the 2-day systemic bactericidal antibiotic treatment is concluded from the fact that all the blood cultures were sterile on day 2. On day 5 only 1 of the 22 blood cultures was dubiously positive; all of the 15 liver cultures on that day were sterile.

A very low incidence of infections with Gram-negative bacteria was found in animals treated according to our new protocol, in comparison with experimental autotransplantation (Alican and Hardy, 1967) and homotransplantation experiments (MacSween, 1969; Dent et al., 1971). Clinically manifest cholangitis was never diagnosed with

† Four animals alive 1 year after transplantation.

certainty in groups II and III. Compared with a gallbladder to duodenum anastomosis, the end-to-end common bile duct anastomosis seemed to decrease the incidence of ascending cholangitis, as suggested by Calne (1969) and in accordance with the findings of Brettschneider et al. (1968) and Dent et al. (1971) in autotransplantation experiments in pigs. The feasibility of a common duct anastomosis without splinting or drainage has now been shown in pigs (Calne, 1969), monkeys (Myburgh et al., 1971) and dogs (Krom, 1975); in addition, in all our pigs in which the anastomosis was widened by the spatulation technique, absence of stenosis at the anastomosis site was documented by direct cholangiography. In our opinion this anastomosis should be reconsidered for human transplantations since ascending cholangitis may then be prevented. Liver abscesses were not found in the 27 experiments of groups II and III. One subphrenic abscess was probably a complication of the vagotomy and pyloroplasty operation performed because of a bleeding ulcer. Conceivably, selective decontamination of the bowel decreased portal bacteraemia during periods of liver ischaemia, i.e. the first few days after transplantation and when rejection occurs. Post-mortem liver and blood cultures were positive for *E. coli* in 4 animals, in contrast to the macroscopic and microscopic findings at autopsy. As in 2 animals a blood culture taken on the day before death did not show any growth, we assume that bacterial invasion was a preterminal event. It is of interest that in 3 animals it occurred together with severe hepatic failure due to rejection. In our opinion selective decontamination of the gut should not only be considered before transplantation but also when hepatic failure is diagnosed.

Selective decontamination of the bowel and protective isolation appeared to be rather simple procedures, when facilities for sensitivity testing of faecal flora are available. According to the colony counts in the postoperative faecal specimen, it was effective in nearly all the dogs. In most of the pigs the antibiotic combination neomycin/kanamycin chosen before the result of the sensitivity testing became available was not optimal; cephaloridin/neomycin was a superior combination *in vitro*. This finding emphasizes again the importance of adequate sensitivity testing of the faecal flora in order to obtain successful decontamination. Selective bowel decontamination can probably be performed in the relatively short period available before human liver transplantation; its effect might be enhanced by mechanical bowel preparation. No side effects other than diarrhoea were noted; no evidence was found that the procedure led to resistant strains or overgrowth with fungi or virus.

All the animals surviving for 2 months lived longer than 1 year and are still alive, except for the pig which died with a subphrenic abscess. The sustained survival contrasts with the experience of others; nearly all authors describe a steady decrease in the survival percentage with an increase in time. Although this decreasing survival percentage has been related to immunological processes, Alican and Hardy (1967) found a survival curve in autotransplantation experiments which appears to be identical to the allograft curves (Calne et al., 1969; Chandler et al., 1972). As infection was the main cause of death in the autotransplantation series, we also suspect infectious complications to be at least as lethal as rejection in the allotransplantation experiments. Consequently, the major factor responsible for the increase in long term survival in our experiments is the great reduction of Gram-negative infections in the acute and late phases of orthotopic liver transplantation.

The relative importance of the various measures used in this study to prevent infections with Gram-negative organisms is still open for discussion. The common duct to common duct anastomosis seems especially important to prevent chronic cholangitis, whereas bactericidal antibiotics and selective bowel decontamination with protective isolation prevent hepatic abscess formation and acute cholangitis with biliary fistula formation, both sequelae of septicaemia during transplantation or acute rejection episodes. Further studies are needed to assess the importance and necessity of these measures for the management of human liver transplant recipients.

Fatal *Clostridium welchii* septicaemia following acute cholecystitis

M. T. CLANCY AND S. O'BRIAIN*

SUMMARY

A case of Clostridium welchii septicaemia following acute cholecystitis is described. The onset was acute and a rapidly fatal outcome ensued. Radiological findings were negative. An approach to the antibiotic treatment and general management is discussed.

THE commonest bacteria isolated from the biliary tract are the aerobic enteric bacteria and facultative streptococci. Among the anaerobes isolated, anaerobic streptococci and *Clostridium* species are the most prominent (Gorback and Bartlett, 1974). In the pre-antibiotic era some investigators found *Cl. welchii* in 10–20 per cent of diseased gallbladders at surgery (Gordon-Taylor and Whitby, 1930). Acute cholecystitis accompanied by *Cl. welchii* septicaemia is rare. The present case is reported to emphasize the serious nature of *Cl. welchii* cholecystitis, the difficulty in establishing a clinical diagnosis and the need to include an appropriate antibiotic in the treatment of this condition.

Case report

A 65-year-old male was admitted to hospital on 2 September 1973 with a 3-day history of right-sided abdominal pain radiating through to the back and shoulders and accompanied by vomiting. He had suffered two similar episodes in the preceding 3 months.

On examination the patient was anicteric, drowsy and flushed. The temperature was 37·3 °C, pulse rate 110/min, blood pressure 170/105 and respiratory rate 24/min. On abdominal examination there was marked tenderness and guarding in the epigastrium and right hypochondrium. Bilateral crepitations were heard at both lung bases. A diagnosis of acute cholecystitis was made.

Investigations carried out were: haemoglobin 16·2 g/dl, WCC $8000/\text{cm}^3$, ESR 25 mm/h; urea and electrolytes were normal except for a serum chloride of 97 mmol/l. Straight X-rays of the abdomen, both erect and supine, showed no evidence of perforation or intestinal obstruction and the gallbladder was not visualized. The chest X-ray showed areas of pneumonia at both bases. Further biochemical investigations were performed on the following day: total serum bilirubin 8·9 mg/100 ml, serum alkaline phosphatase 115 mu./ml, LDH 350 mu./ml, SGOT 154 mu./ml, urea 74 mg/100 ml, potassium 7·8 mmol/l. Serum estimations of chloride, SGOT, amylase and proteins were normal.

On admission the patient was judged to be sufficiently well to be treated with oral tetracycline and probanthine. Eight hours following admission he became dehydrated, drowsy and flushed. His temperature rose to 38·4 °C, pulse rate 130/min, blood pressure 200/110 and the respiratory rate 24/min. A blood culture was taken and he was treated with intravenous fluids and tetracycline. The following morning he had developed jaundice and was clinically shocked. A bluish discoloration of the abdominal wall had developed. Cephaloridine intravenously was started, but his condition deteriorated rapidly and he died less than 24 hours after admission. The following day the laboratory reported that the blood culture grew *Cl. welchii*, Type A, producing alpha and kappa toxins and sensitive to penicillin 2 units, ampicillin 10 µg, cephaloridine 5 µg, erythromycin 15 µg, co-trimoxazole 25 µg and rifamide 10 µg, and resistant to kanamycin 30 µg and tetracycline 10 µg.

At post-mortem examination there was evidence of acute cholecystitis, ascending cholangitis and septicaemia. The gallbladder was thickened and inflamed, containing soft mixed stones, bile and cloudy pale fluid. *Cl. welchii*, Type A, having the same antibiotic sensitivity pattern as the ante-mortem blood culture, was isolated from the gallbladder contents. The common bile duct was slightly dilated and contained soft mixed stones. Several small abscesses were present in the liver. Sections of the gallbladder wall showed extensive oedema and infiltration with polymorphs and mononuclear cells. Sections of the spleen showed a decrease in the numbers of polymorphs in the red pulp, and clostridia were seen lying in the splenic vessels (*Fig.* 1). The only other significant finding was pulmonary oedema.

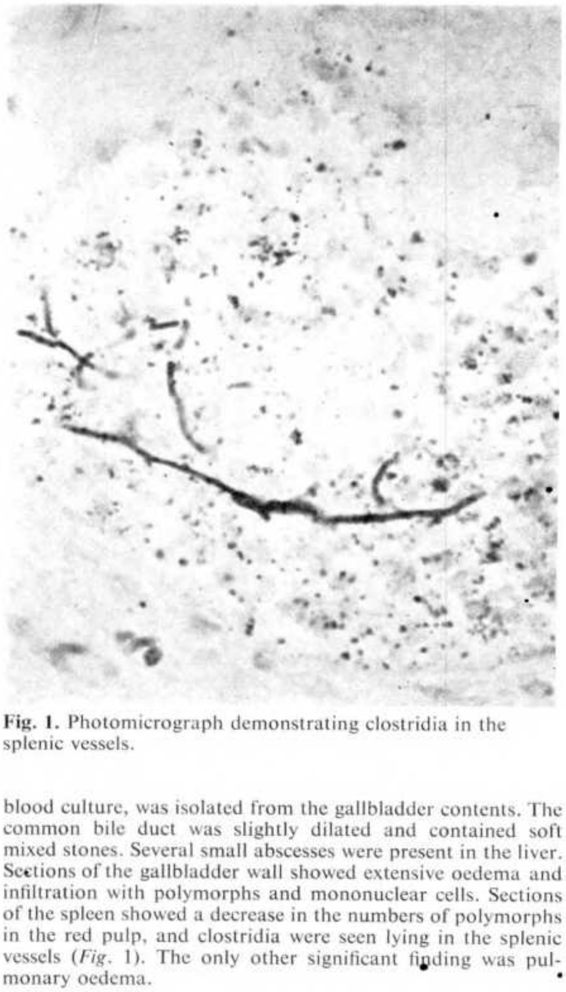

Fig. 1. Photomicrograph demonstrating clostridia in the splenic vessels.

Discussion

Reports of acute cholecystitis with *Cl. welchii* septicaemia are rare and those recorded are set out in *Table I*. The high mortality is noteworthy. Some

unusual features have been described by various authors. In the largest group described by Pyrtek and Bartus (1962), they observed a gradual fall in blood pressure, accompanied by a rising temperature and a disproportionate increase in pulse rate. Bennett and Healey (1963) described acute spherocytic haemolytic anaemia occurring with *Cl. welchii* septicaemia. McKibbin and Parks (1974) reviewed the features of acute emphysematous cholecystitis. This is the terminology most frequently used. A wide variety of organisms has been discovered in reported cases, but at least 50 per cent of cultures revealed a growth of one of the clostridia (Bigler, 1960). McKibbin and Parks (1974) emphasized the importance of demonstrating gas in the gallbladder on a straight X-ray of of the abdomen which is usually evident within 24–48 hours of the onset of symptoms.

All of these reported features were absent in the present case, which raises the importance of early effective antibiotic therapy to include an anticlostridial agent when treating infections of the biliary tract. Unfortunately, X-rays of the abdomen were not repeated in this patient when he suddenly deteriorated 8 hours after admission. Almost certainly a diagnosis of acute cholecystitis due to gas-forming organism would have been made. The bluish discoloration of the abdominal wall which appeared was thought to be indicative of acute pancreatitis. In the light of the post-mortem findings this was, of course, a rapidly spreading myositis of the anterior abdominal wall, and the presence of crepitus over these areas was not recorded.

If these signs had been elicited, and the diagnosis of clostridial septicaemia suspected, prompt intervention with high doses of crystalline penicillin and ampicillin intravenously, to which *Cl. welchii* is extremely sensitive, could have been life saving. The choice of a tetracycline in the early management of this patient was unfortunate; although excreted mainly in the bile many strains are resistant (Johnstone and Cockcroft, 1968), and its use is contraindicated in the presence of jaundice and clinical shock. The changeover to an intravenous cephalosporin came too late; although the minimal inhibitory concentration of *Cl. welchii* for a cephalosporin is 0·4 µg/ml and for penicillin 0·12 µg/ml, the latter still remains the antibiotic of choice in the therapy of anaerobic infections due to this gas-forming organism. Finally, it is regrettable that facilities for the use of hyperbaric oxygen were not available. It is particularly effective in reducing the mortality from gas gangrene by preventing the production of alpha toxin and bacterial reproduction.

The removal of retained gallstones from the common bile duct: experience with sodium cholate infusion and the Burhenne catheter

D. C. BRITTON, B. S. GILL, R. M. R. TAYLOR AND OLIVER JAMES*

SUMMARY

The use of cholic acid T tube infusion and of the Burhenne catheter has been investigated in the management of gallstones retained in the common bile duct following biliary surgery in 9 patients. Four of 7 patients treated with cholic acid infusion showed disappearance of the stones during treatment. The stones in a fifth subject were removed by a combination of cholic acid infusion (1 stone disappeared) and instrumentation with a Burhenne catheter (a second stone removed). Use of a Burhenne catheter was unsuccessful in 3 of 4 patients. Details of the technique of cholic acid infusion are given, and possible complications of the treatment are discussed. The use of cholic acid infusion for the dissolution of stones in the common bile duct is recommended.

In spite of the use of routine preoperative cholangiography (Lawson and Gunn, 1970; McEvedy, 1970; Wheeler et al., 1970), Fogarty biliary balloon probes (Fogarty et al., 1968) and fibre-optic choledochoscopy, calculi retained in the biliary tree after gallbladder surgery are still a serious problem. Stones are left in the common bile duct in over 2 per cent of biliary tract operations (Colcock and McManus, 1955; Magee and Macduffee, 1968; Sandblom, 1972; Way et al., 1972). In some instances retained stones are discovered by postoperative cholangiography. In others the presence of an impacted stone may be known to the surgeon before completion of an operation but further trauma to the common bile duct is deemed inadvisable. In a few cases falsely interpreted peroperative cholangiography has led to error.

Retained stones may pass spontaneously following an operation while the T tube is still in position, but if they do not, surgical removal has, in the past, been necessary. This may be a difficult undertaking and has led to the use of such supplementary primary procedures as biliary fenestration (Capper, 1961; Margarey, 1966) or routine transduodenal sphincterotomy to avoid the need for re-exploration.

Recently, two techniques have been reported which may allow removal of retained calculi via the T tube or T tube tract without further surgery. The first is the instrumental removal of the stone via the T tube tract (Mazzariello, 1970; Margarey, 1971; Burhenne, 1973); the second depends upon the dissolution of the stones by instillation of bile salts down the T tube (Way et al., 1972; Lansford et al., 1974).

In this paper the use of sodium cholate infusion, manipulation of stones with a Burhenne catheter and a combination of these methods is reported in the management of 9 patients with stones retained in the common bile duct referred by a number of surgeons.

Patients and methods

Nine patients were studied 3–16 weeks after cholecystectomy and exploration of the common bile duct. In 6 subjects the stones were distal to the T tube. In all the patients the stones were radiolucent and had been demonstrated in at least two T tube cholangiograms prior to treatment. Liver function tests (serum alkaline phosphatase, SGOT and bilirubin) showed consistent obstructive features before treatment in each case. Informed consent to the procedures was obtained from each patient.

Sodium cholate infusion (Way et al., 1972)

Four patients received infusions of sodium cholate alone, 3 patients received infusion of sodium cholate followed by instrumentation with a Burhenne catheter and 2 patients had instrumentation with a Burhenne catheter alone.

A sterile solution of 100 mM sodium cholate buffered to pH 7·5 was prepared as follows: cholic acid 408 g, sodium hydroxide 38 g, sodium chloride 90 g and distilled water to 10 litres.

The irrigation fluid is manufactured using cholic acid (Biochemical grade; Weddell Pharmaceutical). If the pH of the final solution is found to be slightly acid, it is adjusted using sodium hydroxide to pH 7·5. On occasion the pH has been found to be on the alkaline side of 7·5. In this case it is adjusted to pH 7·5 using up to 14 g of extra cholic acid. This gives a 3·5 per cent excess of cholic acid. The irrigation fluid is then sterilized by filtration through a Sartorius Membranfilter 'Speed flow system', SM162/68. The pressure filter holder containing a Membranfilter pore size 0·45 μ and 142 mm diameter is sterilized by autoclaving at 121 °C and 151 p.s.i. for 30 minutes.

A long radio-opaque intravenous catheter (E–Z Cath 2254 16 Ga 18 in Deseret) was passed down the T tube under fluoroscopic control to the junction of the T tube, and the catheter was tightly secured in position to avoid leakage of sodium cholate back out of the T tube. The catheter was connected to the sodium cholate solution via central venous pressure manometer tubing. The vertical manometer tube was

kept in continuity with the system and was shortened to provide free overflow at about 40 cm above the common bile duct (*Fig.* 1). A flow rate of approximately 30 ml/h (8 drops/min) was used. The infusion was continued for up to 12 days. Cholangiograms were carried out at intervals of 4 days.

Daily estimations of liver function tests, serum electrolytes and serum amylase were carried out. Cholestyramine 4 g 3-hourly was given from the start of treatment. Metoclopramide 10 mg was given if vomiting occurred. If a patient reported pain the infusion was stopped until the pain settled. If the manometric pressure exceeded 40 mm of the solution and overflow from the top of the manometer occurred the infusion was stopped and the catheter was aspirated. Plugs of mucus were removed frequently from the common bile duct.

*Burhenne catheter**

The T tube was removed after confirmatory T tube cholangiography. The Burhenne catheter was then passed down the T tube tract under image intensification control and manipulated into the common bile

Table I: RESULTS OF TREATMENT

Treatment	Case	Site of stone(s)	Result
Sodium cholate infusion	1	Distal	Successful
	2	Distal	Successful
	3	Distal	Successful
	4	Distal	Successful
Sodium cholate infusion + Burhenne catheter	5	Proximal + distal	Sodium cholate 'removed' distal stone; Burhenne catheter removed proximal stone—successful
	6	Mobile	Sodium cholate failed; Burhenne catheter successful
	7	Proximal	Failed
Burhenne catheter	8	Proximal	Failed
		Distal	Failed

Table II: COMPLICATIONS AND SIDE EFFECTS

Treatment	Complication	No. of patients affected
Sodium cholate infusion	Diarrhoea	7/7
	Vomiting	7/7
	Pain + ? ampullary impaction	4/7
Burhenne catheter	Biliary peritonitis	1/5

duct. A Dormia basket was passed through the catheter, the stones were ensnared in the mesh of the basket and the basket was removed. If the procedure was successful liver function tests and repeat cholangiography were carried out. In unsuccessful cases laparotomy and re-exploration of the common bile duct were undertaken.

Results

In 4 out of 7 patients initially treated with sodium cholate solution the stones disappeared 8–12 days after starting the infusion (*Fig.* 2, *Table I*). In a further subject one stone disappeared following infusion but a second larger stone just proximal to the T tube failed to disappear; this stone was successfully removed by a Burhenne catheter. In a sixth patient sodium cholate infusion was ineffective but instrumentation succeeded in removing the stone. Two attempts at using a Burhenne catheter alone failed. In one of these subjects the stone was firmly impacted at the ampulla of Vater.

Complications and side effects

All the patients treated with sodium cholate experienced diarrhoea (*Table II*); this was lessened by the use of cholestyramine but was often quite severe. All the patients who received sodium cholate also became nauseated, anorexic and vomited intermittently despite treatment with metoclopramide. Although 4 of the 7 patients experienced abdominal pain at some time during the infusion this was never severe and in no case was there an associated elevation of serum amylase. In 1 subject successful treatment of the common bile duct stones with sodium cholate solution was followed by biliary peritonitis after removal of the plastic T tube. At operation moderate fibrosis around the common bile duct was found. A further case o biliary peritonitis occurred 2 hours after use of Burhenne catheter and Dormia basket. This wa thought to be due to rupture of the T tube tract. Ther were no deaths or long term complications.

Discussion

It is now widely recognized that peroperative cholangiography should be carried out during all routin cholecystectomies. In patients in whom the commo bile duct has been explored and T tubes inserted int the duct it is important to perform cholangiograph via the T tube before the operation is conclude rather than 1 week later. Radiology used in this wa may reduce the frequency with which gallstones ar mistakenly left in the common bile duct. Nevertheless cases will still occur and any method of removin retained gallstones without a second laparotomy i worth investigating.

While several substances have, in the past, been said to dissolve cholesterol gallstones none has been proved to be effective. Earnest and Admirand (1971) and Farrell et al. (1973) have shown that cholesterol gallstones may be reduced by up to 35 per cent by weight when suspended in bile salt solutions. It is postulated that the effect of cholic acid infusion may be to reduce the size of stones and possibly to make them break into smaller particles which may then be passed out of the common bile duct. The action may, therefore, be a combination of dissolution and subsequent flushing out of the common bile duct. Farrell et al. (1973) showed that cholesterol stones dissolved more readily in bile salt and phospholipid mixtures than in bile salt solution alone. *In vivo* phospholipid is added to the system by the patient's own bile.

The main side effects of cholic acid infusion were nausea, vomiting and diarrhoea. All the patients felt unwell during the infusion, but no marked electrolyte disturbances were noted during treatment. Metoclopramide and cholestyramine alleviated symptoms of nausea and diarrhoea respectively.

Much attention has been focused on the possible hepatoxicity of the oral bile salts, but significant hepatotoxicity is extremely unlikely with cholic acid treatment since (*a*) it is only given for a short time, and (*b*) cholic acid is 7-α-dehydroxylated to deoxycholic acid in the colon; while chenodeoxycholic and particularly lithocholic acids have been shown to be hepatotoxic in many species (Palmer, 1972) the same has not been shown for cholic and deoxycholic acid. Liver function tests have remained normal for up to 1 year after treatment in all the patients following cholic acid infusion.

In neither instance where the stone was proximal to the T tube did dissolution with cholic acid occur (*Cases* 5 and 7). This confirms the finding of Lansford et al. (1974). It may be that this is because there is a poorer stream of cholic acid on these stones than on those distal to the T tube.

The use of the Burhenne catheter has been enthusiastically advocated by several authors with outstanding results. It was used in the present study on a very small number of patients but the results are not so encouraging. In 1 patient use of a Burhenne catheter led to a biliary peritonitis and subsequent laparotomy. However, in 2 subjects a Burhenne catheter was used to remove stones successfully following cholic acid treatment. If cholic acid treatment is considered this must be carried out before removal of the T tube and therefore before use of a Burhenne catheter and Dormia basket.

Conclusion

The objective of this paper was to provide a practical guide to surgeons who may infrequently encounter the problem of stones retained in the common bile duct following surgery. Use of sodium cholate infusion is simple and needs little expertise apart from the ability to manage side effects. The successful use of the Burhenne catheter, however, appears to require considerable practice and expertise and this instrument should perhaps be reserved for centres with particular interest in its use.

Long term changes in total body water, total exchangeable sodium and total body potassium before and after ileostomy

G. L. HILL, J. C. GOLIGHER, A. H. SMITH AND W. S. J. MAIR*

SUMMARY

In 10 patients with inflammatory bowel disease, total body water, total body potassium and total exchangeable sodium were measured both before and 6 months after the establishment of a permanent ileostomy. All 10 patients underwent elective surgery for their inflammatory bowel disease but all were malnourished before surgery when their body composition was first measured.

Six months later, when the body composition was again determined, all the patients were in good health and had normally functioning ileostomies. As a group they had gained 6·8 kg in body weight and 372 mEq total body potassium over the 6-month period. When the 'normal' total body water was calculated for each patient, a deficit of 12·4 per cent for the group was found before surgery and this was still present (11·1 per cent) 6 months later. The concentration of exchangeable sodium in the body water fell from an abnormally high level before surgery to within the normal range 6 months later.

These data show that deficits in total body water occurring preoperatively are not repaired in the months following the establishment of a well-functioning ileostomy, and that a reduction of total exchangeable sodium is present in patients with an ileostomy who are otherwise well. It is suggested that these findings should encourage the surgeon managing patients with intractable inflammatory bowel disease to strive for good nutrition and normal body composition before embarking on excisional surgery and the establishment of a permanent ileostomy.

CONVALESCENCE after proctocolectomy and ileostomy for inflammatory bowel disease is usually marked by rapid weight gain and substantial improvement in the well-being of the patient. After some months he is usually back at work and living an almost normal life.

In spite of this apparent excellent health, there is strong evidence that ileostomy patients who are otherwise well are chronically dehydrated and sodium depleted. Not only has diminished renal excretion of water and sodium been demonstrated in ileostomy patients (Gallagher et al., 1962; Kanaghinis et al., 1963; Clarke et al., 1967) but direct studies of body composition have shown a reduction of total body water and a deficit in total exchangeable sodium (Clarke et al., 1967).

The present study, which measures body composition in a group of patients both before ileostomy and 6 months later, examines these changes in body composition more fully.

Patients and methods

Ten patients who underwent elective ileostomy for inflammatory bowel disease were investigated. Clinical data and the operation performed on each patient are shown in *Table I*. At the time of operation all the patients were chronically ill and unable to work because of the bowel symptoms. All had suffered considerable weight loss (*Table I*).

Total exchangeable sodium was measured by the method described by Veall and Vetter (*1958*) using the radioactive isotope ^{24}Na. Total body water was determined by the dilution of a volume of tritiated water estimated from two plasma samples taken 3 and 6 hours after oral administration. Total body potassium was measured by the whole body counter method described by Burkinshaw (1967) from these laboratories.

Two days prior to surgery each patient was interviewed, physically examined and weighed. Serum sodium and potassium were estimated using a Technicon Autoanalyzer (SMA/660). The total body potassium was then estimated using a whole body counter.

The following day, i.e. the day before surgery, 30 μCi ^{24}Na diluted in physiological saline and 200 μCi tritiated water were dispensed into a plastic cup and drunk together with several rinsings by the patient. At 3 and 6 hours later 10 ml of venous blood were taken and stored in a heparinized tube. The blood samples were distilled (Vaughan and Boling, 1961) and duplicate 1-ml aliquots were added to 10 ml NE220† and measured in a Packard Liquid Scintillation Counter (Series 300), together with appropriate standards and blanks. Total body water (TBW) was then calculated from the formula:

$$\text{TBW (litre)} = \frac{\text{Total counts of tritium administered}}{\text{Counts/litre of serum water (extrapolated to time of administration)}}.$$

Twenty-four hours after the administration of the sodium isotope, 20 ml of venous blood were taken and stored in a heparinized tube. The volume of the 24-hour urine collection was measured and a 10-ml aliquot taken for measurement. The ^{24}Na content of the serum and urine was measured using a NaI

NS, Not significant.

scintillation counter together with appropriate standards and blanks. The concentration of sodium in the serum and urine was determined and the total exchangeable sodium (Na_E) was calculated from the formula:

$$Na_E = \text{Na space (litre)} \times \text{serum Na (mEq/litre)}.$$

For the total body water estimate the total experimental standard deviation, including dispensing calibration, counting and reproducibility, was not greater than ±3 per cent (Williams et al., 1964). The coefficient of variation of the estimate of total body potassium for a typical man was 3·2 per cent and for a typical woman 3·4 per cent (Burkinshaw, 1967).

Results

General health

At 6 months all the patients claimed good health and had either resumed or were about to resume their normal occupation. On physical examination each patient was found to be physically fit apart from an incompletely healed perineal wound in patient 6 and a degree of tiredness and depression in patient 10. There was no evidence of recurrent disease in any of the patients. A full blood count and serum electrolyte profile for each patient were within the normal ranges.

Body weight and total body potassium

Table II shows the changes in body weight over the 6-month period. Apart from patients 4 and 10 in whom the body weight remained at the preoperative level, the rest of the group had an appreciable weight gain. However, only 4 patients (2, 3, 8, 9) had returned to what they considered was their ideal pre-illness weight. The group as a whole had a mean weight gain of 13·7 per cent (6·8 kg, $P<0·005$) over the 6-month period. There was a similar increase in total body potassium. *Table II* shows that, apart from patients 4 and 10, the patients had a substantial gain in total body potassium when measured 6 months after the operation. The group of patients as a whole had an overall mean gain in total body potassium of 15·5 per cent (372 mEq, $P<0·02$) 6 months after surgery.

The total body potassium/total body water ratio (*Table III*) remained constant for each patient apart from patient 6, in whom the increase in ratio at 6 months indicates a return to a more normal value.

Total body water and 'normal' total body water

Table II shows that there has been a mean gain in total body water of 14·3 per cent (4 litres, $P<0·02$) for the group at 6 months. The ratio of total body water/body weight (*Table III*) remained constant for all the patients except patient 1, in whom a falling water fraction indicates a disproportionate gain in body fat and total body solids.

The relationship between total body potassium and total body water is well known (Talso et al., 1960; Hughes et al., 1967; Delwaide and Crenier, 1973) and has been used to predict variations from normality, using the measured total body water to determine potassium deficiency (Hughes et al., 1967), and total body potassium to estimate water deficiency (Smith, 1965). Data obtained previously in this laboratory (Hughes et al., 1967) have been used to predict the 'normal' total body water of the 10 patients using their total body potassium measurement. The results shown in *Table IV* indicate a mean reduction in body water compared with the normal state of 12·4 per cent before ileostomy and 11·1 per cent 6 months after ileostomy.

Total exchangeable sodium

As a group the patients did not demonstrate an absolute increase in total exchangeable sodium over the 6-month period (*Table II*) although 3 individuals did so (patients 5, 8, 9).

The ratio of total exchangeable sodium/total body water (*Table III*) fell from an abnormally high level preoperatively (mean 86·7) to within the normal range (Moore et al., 1963) at 6 months (mean 76·5, $P<0{\cdot}05$).

The patients (1, 2, 5, 6, 7) (*Table I*) on steroids preoperatively had a higher total exchangeable sodium/total body water ratio when measured at this time than those not on steroids, although this difference is not statistically significant (91·4 ± 6, cf. 81·9 ± 7).

Discussion

Measurement of total exchangeable sodium, total body water and total body potassium revealed considerable variations from patient to patient. Nevertheless, it was possible to demonstrate that 6 months after ileostomy when nutritional equilibrium had been regained and the patients looked fit and well there were deficits in both total body water and total exchangeable sodium.

In spite of a mean weight gain of 6·8 kg and an increase in total body potassium of 372 mEq, a persisting deficit of 11–12 per cent of total body water remained 6 months after ileostomy. Whereas the concentration of sodium in body water was abnormally high preoperatively, this returned to within the normal range 6 months later. The normal total exchangeable sodium/total body water ratio at 6 months, together with a persisting reduction in total body water, indicates a deficit of total exchangeable sodium of similar magnitude to that of total body water. This deficit developed during the 6-month period following operation.

These findings of salt and water depletion occurring in patients with an ileostomy are in accord with a previous report (Clarke et al., 1967). This showed a 7 per cent deficit in total exchangeable sodium and an average reduction of 11 per cent in total body water in patients with a well-established ileostomy when compared with a control group.

The present study defines these deficits more completely. The total body water reduction is found in the preoperative colitic patient and persists after ileostomy, whereas the total exchangeable sodium deficit tends to develop after the ileostomy has been established.

Six months after ileostomy all the patients had normal ileostomy function and none appeared clinically dehydrated (Hill, Mair and Goligher 1974). Renal conservation of sodium was present in these patients, and those without an ileal resection showed intestinal conservation of sodium and water. Presumably, therefore, the failure to regain body water and the loss of body sodium are reflections of a chronic salt- and water-losing state to which the conservation processes of the body have responded incompletely. It is interesting that in colitic patients who have an ileorectal anastomosis instead of an ileostomy the rectum retains sufficient absorptive function that normal body composition is regained and maintained (Hill, Watts et al., 1974).

Thus it appears that a severe water deficit occurring in the colitic patient prior to surgery is not repaired after excision of the diseased bowel and a satisfactory ileostomy is established. This study supports the postulate that the water deficit is primary and the sodium changes alter in the months following surgery to regain normal body tonicity.

It is a clinical observation that the colitic patient who is nutritionally competent before surgery makes better progress and is stronger and healthier in the weeks and months following proctocolectomy than his counterpart who is severely malnourished at the time of operation. It seems probable that a water deficit is less likely to develop in the ileostomy patient who is nutritionally well prior to surgery, but we are unable to comment on this because none of the patients in the present study were hyperalimented before surgery, either by parenteral nutrition or by an elemental diet. Nevertheless, these data should encourage the surgeon managing patients with intractable inflammatory bowel disease to strive for good nutrition and normal body composition before embarking on excisional surgery and the establishment of a permanent ileostomy.

Acknowledgements

The authors express their appreciation to several colleagues for helpful discussion, to Dr L. Burkinshaw and Miss D. W. Krupowicz, Department of Medical Physics, for the whole body potassium measurements and to Dr C. J. Hayter, Consultant Physician, Department of Nuclear Medicine, for his continual encouragement.

Results of surgery for Crohn's disease in the Glasgow region, 1961–70

S. YOUNG, I. S. SMITH, J. O'CONNOR, J. R. BELL AND G. GILLESPIE*

SUMMARY

During the period 1961–70, 283 patients in the Glasgow region have been studied with regard to the outcome of 418 surgical procedures performed for Crohn's disease.

Resection was followed by an overall recurrence rate of 33 per cent, but in disease confined to the large bowel the rate was 18 per cent.

Exploratory operations and bypass procedures were followed by a recurrence rate of 70 per cent. Evidence is provided that recurrence following bypass procedures for small bowel disease and ileocolitis occurs at a later stage than after exploratory operations alone.

By the end of the study period 77 per cent of patients in this series had required one or more resections.

CHRONIC Crohn's disease of the small or large bowel is a condition which tends to undergo spontaneous relapse and remission. Although supportive medical therapy may be helpful in providing symptomatic relief, it is not curative and most patients eventually come to operation (Colcock, 1964; Jones et al., 1966; Slaney, 1968; Banks et al., 1969; Edwards, 1969; de Dombal et al., 1974). As this disease has increased in incidence (Norlen et al., 1970; Fahrlander and Baerlocher, 1971; Kyle, 1971; Smith et al., 1975), the surgical management of the condition in the Glasgow region during the decade 1961–70 has been examined with particular reference to the mortality, morbidity and the likelihood of subsequent recurrence.

Patients and methods

For the purpose of this study the Glasgow region may be defined as that area in West Scotland 25 miles in diameter, centred on the City of Glasgow. The population of this area amounts to 1·7 millions, for whom hospital facilities are provided by 12 Health Service Hospitals. Patients admitted to these hospitals during the decade with a diagnosis of Crohn's disease were identified by reference to the inpatient hospital statistics of the Scottish Home and Health Department, which has recorded all Scottish hospital admissions since 1961.

Following examination of the case records, the diagnosis of Crohn's disease was accepted only if the clinical and radiological features were supported by histological features as described by Morson (1971) and/or operative appearances indicative of transmural inflammatory bowel disease. Thus, 283 patients who had undergone one or more surgical procedures varying from biopsy or laparotomy to intestinal bypass or resection satisfied these criteria. These included 245 patients diagnosed between the years mentioned above and 38 patients diagnosed before 1961. As the follow-up extends to the end of 1971, the period of follow-up ranges from 1 to 23 years. For analysis these patients have been classified into three groups according to the site or sites of initial bowel involvement as shown in *Table I*.

Table 1: SITE OF CROHN'S DISEASE AT INITIAL DIAGNOSIS

Group	Site of disease	No. of cases	%
1	Small bowel only	155	55
2	Ileocolitis	81	28
3	Large bowel only	47	17

Table II: INDICATIONS FOR INITIAL SURGERY

Indication	Small bowel (*n* = 155) %	Ileocolitis (*n* = 81) %	Large bowel (*n* = 47) %	Total (*n* = 283) %
Obstruction	35	25	4	27
Fistula	5	9	24	9
Severe alimentary symptoms	41	43	53	44
Suspected appendicitis	12	13	4	11
Failed medical treatment	7	10	15	9

Indications for initial surgical procedures and subsequent admissions

Initial surgery

The data in *Table II* classify the 283 patients according to what appeared to be the main indication for the initial surgical procedure. These may be resolved into those of an emergency nature for acute symptoms (66) and those of a more chronic nature leading to elective surgery (217).

Fifty-five of the 66 patients who had emergency surgery in their first attack proved to have chronic Crohn's disease confined to the small bowel and accounted for one-third of this whole group (group 1). The most frequent indication was a diagnosis of acute appendicitis or of intestinal obstruction. In the former case surgery was often confined to appendicectomy or drainage of an abscess; in the latter more definitive surgery for Crohn's disease was undertaken. In 6 cases a perforation of the distal ileum or caecum in association with chronic Crohn's disease was the cause of the acute presentation.

Table III: INDICATIONS FOR SUBSEQUENT ADMISSIONS

Indication	Small bowel ($n = 99$) %	Ileocolitis ($n = 47$) %	Large bowel ($n = 29$) %	Total ($n = 175$) %
Obstruction	30	16	10	23
Fistula	20	29	24	23
Severe alimentary symptoms	38	45	62	44
Abscess	6	5	0	4
Anaemia/weight loss	6	5	4	6

Elective surgery was also performed to relieve patients with intestinal obstruction of a more subacute or chronic nature. Many of these patients had already had a trial period of medical treatment and the signs of obstruction merely precipitated surgery. Similarly, the presence of a fistula of the abdominal wall or in the perineum provided the immediate indication for a surgical procedure in 9 per cent. In 44 per cent with 'severe alimentary symptoms' operation was undertaken because of persisting abdominal pain, often associated with diarrhoea or weight loss (20 patients were suspected of having malignant disease), in the hope that a surgical procedure might be curative or relieve their more clamant symptoms.

In the remaining 9 per cent elective surgery was undertaken because these patients had become gastrointestinal cripples due to continued weight loss and diarrhoea in spite of apparently adequate conventional supportive medical treatment.

Subsequent admissions

Table III indicates the main reason for subsequent admissions which were followed by a period of supervised medical treatment or further surgery.

In each case a diagnosis of chronic Crohn's disease had already been made macroscopically or histologically, so that subsequent surgery, where necessary, was usually elective. The indications for surgery assumed a similar pattern, displaying little alteration in the proportions of patients showing signs of either intestinal obstruction or severe alimentary symptoms. There was, however, a marked rise both in the overall numbers and in the proportion of patients with fistula.

Surgical procedures

Three main types of surgery were used in the treatment of patients in this series, namely laparotomy/biopsy, bypass surgery and resection. This study was not prospectively planned and therefore patients undergoing each form of surgery were not deliberately matched. However, patients undergoing surgery for Crohn's disease in the more common sites (i.e. small bowel disease and ileocolitis), forming 83 per cent of the total series, were comparable for mean age, general condition and extent of disease, though a somewhat higher incidence of skip lesions was observed among patients undergoing resection. In the patients with lesions confined to the large bowel (17 per cent), although there was a preponderance of elderly females, there were likewise no differences among patients having each form of surgery.

Laparotomy

a. Small bowel lesions: Thirty patients with small bowel Crohn's lesions had laparotomy at the initial surgical procedure. Twenty-one patients (70 per cent) have already been readmitted with a major recurrence at a mean of 1 year later (6 months to 6 years), and 19 of these have required further operation (resection 12, bypass 7).

b. Crohn's ileocolitis: Ten patients had laparotomy and 4 had anal or rectal biopsy as the initial surgical procedure. Ten patients (71 per cent) have been readmitted with a major recurrence at a mean of 2 years later (3 months to 4 years), and 7 of these have required further surgery (laparotomy/biopsy 4, bypass 2, resection 1).

c. Large bowel lesions: Fifteen patients had confirmation of diagnosis either by laparotomy (2) or by anal or rectal biopsy (13) as the initial surgical procedure. Ten (66 per cent) have been readmitted with major recurrence at a mean of 1 year later (3 months to 2½ years), and 8 of these have required definitive surgery (bypass 5, resection 2, laparotomy/biopsy 1).

Bypass surgery

a. Small bowel lesions: Thirty-two patients had bypass in continuity as the initial surgical procedure. Nineteen (61 per cent) have been readmitted with a major recurrence at a mean of 5 years later (4 months to 26 years), and 18 of these required further surgery (resection 14, bypass 3, laparotomy/biopsy 1).

Six patients had bypass with exclusion as the initial surgery. No recurrences have so far been observed in a 1–5-year follow-up.

b. Crohn's ileocolitis: Nine patients had bypass in continuity as the initial surgical procedure. Eight patients (82 per cent) have since had a major recurrence of whom 4 have required further surgery (resection). Bypass with exclusion was the initial operation in 5 patients, of whom 2 have required further surgery (resection).

c. Large bowel lesions: Seven patients had colostomy without resection as the initial surgical procedure. Four (59 per cent) have been readmitted with a recurrence at a mean of 9 months later (4–20 months), and 3 of these required further surgery (resection).

Resection

a, Small bowel lesions: Eighty-seven patients had resection as the initial surgery. Thirty (37 per cent) patients have been readmitted with recurrence at a mean of 5 years later (3 months to 20 years), and 20 of these have required further surgery (resection 12, bypass 3, laparotomy/biopsy 5).

b. Crohn's ileocolitis: Fifty-three patients had resection as the initial procedure. Eighteen (34 per cent) patients have been readmitted with recurrence at a mean of 5 years later (1 month to 14 years), and of these, 14 have required further surgery (resection 8, laparotomy or biopsy 5, bypass 1).

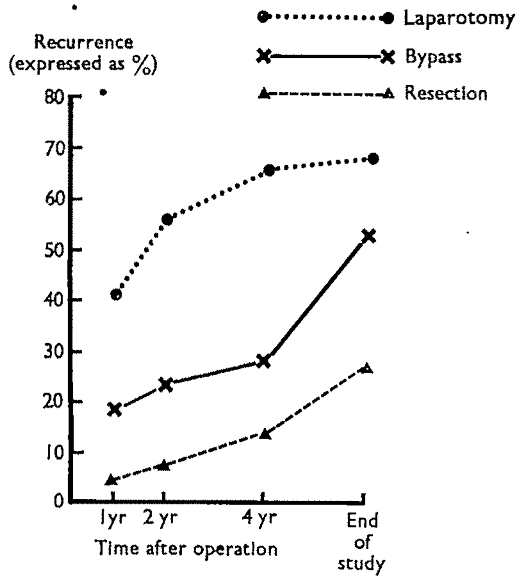

Fig. 1. Incidence and time of recurrence after surgery for small bowel Crohn's disease.

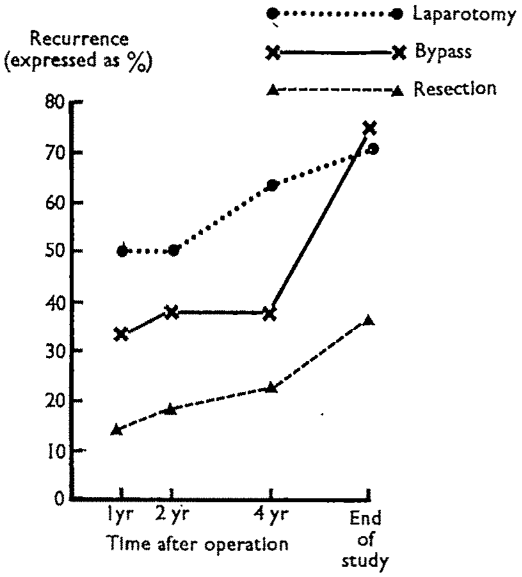

Fig. 2. Incidence and time of recurrence after surgery for Crohn's ileocolitis.

Table IV: RECURRENCE AFTER INITIAL SURGERY

Type of surgery	Small bowel %	Ileocolic %	Large bowel %
Laparotomy/biopsy	70	71	67
Bypass or colostomy	51	77	57
Resection	37	34	18

c. *Large bowel lesions*: Twenty-five patients had an elective resection as the initial surgical procedure. Four (18 per cent) have been readmitted with recurrence at a mean of 1 year later (3 months to 5 years), and 2 of these have required further surgery (resection).

By the end of 1971, 123 of 155 (80 per cent) patients with small bowel lesions had undergone one or more resections; 63 of 81 (77 per cent) patients with Crohn's ileocolitis and 33 of 47 (70 per cent) patients with large bowel lesions had likewise had one or more resections.

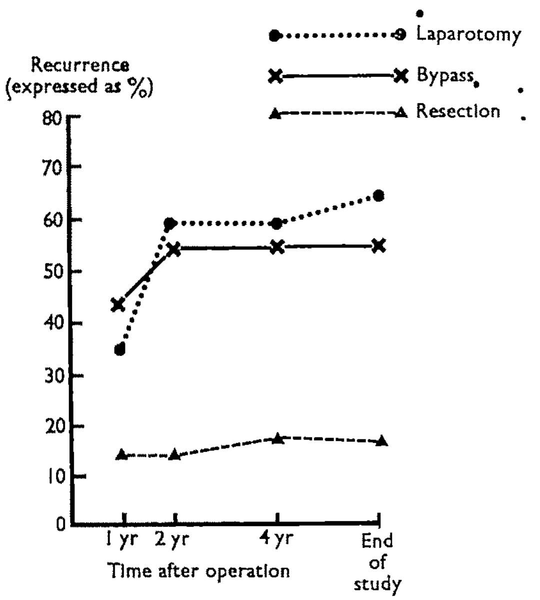

Fig. 3. Incidence and time of recurrence after surgery for large bowel Crohn's disease.

Recurrence after initial surgery

In this study a recurrence was defined as further major symptoms either resulting from recrudescence or complications of the disease at the original site or resulting from extension of the pathological process to involve other areas, proved by radiology, surgical operation or histology and requiring inpatient hospital stay. The follow-up period ranged from 1 to 26 years. The incidence of recurrence has been expressed as a percentage of the surviving patients in each category and is shown in *Table IV*.

The incidence of recurrence after exploratory laparotomy or bypass procedures is high for lesions in all sites. Following resection, however, recurrence is appreciably less common, especially for large bowel lesions.

Time of appearance of recurrences

The time at which recurrent disease occurs after the three main types of surgery is of interest and *Figs.* 1, 2 and 3 show the recurrences, expressed as percentages, which have occurred at 1, 2 and 4 years after surgery in patients with small bowel lesions, ileocolitis and large bowel lesions respectively. It is clear that by 4 years after laparotomy the number of recurrences for patients with small bowel lesions and ileocolitis has virtually reached the level observed at the end of the study period, and that this occurs even earlier at around 2 years when large bowel lesions are considered. However, it is noteworthy that at the same stage the incidence of recurrence after bypass surgery for patients with small bowel lesions and ileocolitis has only reached 50 per cent of the final observed recurrences at the end of the study.

Assessment of recurrences after secondary operations is only meaningful for further resections in patients with small bowel lesions since only this group contained adequate numbers for analysis. The recurrences at 1, 2 and 4 years showed a similar pattern to those seen after initial resection.

Postoperative complications

Perforation: Four patients had free perforations of bowel within 10 days of a surgical procedure. All occurred either in skip lesions or in segments of bowel involved by Crohn's disease but left *in situ* at the initial operation. One had jejunal perforation following a colonic resection; 2 patients had multiple perforations of ileum, in one case after laparotomy and in the other proximal to an anastomosis while continuing on steroid therapy; the fourth patient had free caecal perforation after more distal colonic resection and anastomosis.

Fistula formation: Thirty patients (11 per cent) developed an external fistula after operation. Twelve followed laparotomy with or without appendicectomy, 10 followed a bypass procedure and 8 followed resection.

Of the external fistulas occurring after laparotomy with or without appendicectomy, 8 followed drainage of an abscess in the right iliac fossa and 4 of these were proved to have arisen from diseased ileum, including the only case occurring after appendicectomy. Four of those occurring after bypass surgery were likewise shown to arise from diseased ileum.

Where surgical correction of the fistula was required, resection of the affected segment of bowel (18) and bypass with exclusion (1) were immediately successful. Three closed after excision of the track alone, but only after a long interval. Bypass in continuity was equally unpredictable, failing in 1 patient and succeeding in 2 after a delay of over 6 months. Gradual closure was obtained by using azothiaprine in 2 patients.

Anastomotic leakage: This occurred on 10 occasions and led to 9 postoperative deaths at an average of 12 days after surgery. All but one occurred after resection with end-to-end anastomosis. Four occurred after ileal resection, 3 after right hemicolectomy and 2 after left colon resection.

Postoperative mortality

Postoperative mortality refers to deaths within 28 days of surgery, performed during any admission. The 283 patients in this series had a total of 418 surgical procedures. There were 21 postoperative deaths. Ten of these resulted from anastomotic leakage after resection. Laparotomy was attended by a 7 per cent mortality, bypass surgery 2 per cent and resection 5 per cent.

There were 7 additional late related deaths; 2 from malabsorption, 2 from mesenteric vascular occlusion, 1 from sepsis, 1 from anaemia requiring transfusion and 1 from perforation of a gastric ulcer while on steroids. Ten late unrelated deaths occurred.

Extension of disease

At the time of initial diagnosis 55 per cent of patients had disease confined to the small bowel, 28 per cent had Crohn's ileocolitis and 17 per cent had disease confined to the large bowel. However, by the time of review at the end of the study period in 1971, only 47 per cent had disease confined to the small bowel, whereas 39 per cent had ileocolitis and 13 per cent had disease confined to the large bowel, indicating extension of the disease, most often into a more distal portion of the alimentary canal.

Discussion

Indications for surgery in Crohn's disease may be single or multiple, but in this review we have presented what we believe to have been the main indication both for the primary surgical procedures and for subsequent admissions with major symptoms. The most frequent indication for elective surgery in the present series was 'severe alimentary symptoms' (44 per cent), but if the patients who required surgery because of failure to respond to medical treatment (9 per cent) are included, then over 50 per cent of the present series came to surgery because of distressing alimentary symptoms or other uncontrolled medical problems. De Dombal et al. (1971a) also observed a preponderance of patients (81 per cent) requiring surgery for 'chronic disease'.

Many patients in this series who had varying degrees of intestinal obstruction also had other intestinal symptoms, but in such cases obstruction has been taken as the principal indication. It is of interest, therefore, that in the Glasgow region intestinal obstruction was the indication for initial surgery and for subsequent readmission in only 26 and 23 per cent of patients respectively. Similar findings of 20 and 30 per cent respectively have been reported from Leeds (de Dombal et al., 1971a). In the United States, however, the incidence of obstruction as the prime indication for initial surgery and for subsequent readmission appears to be much higher, for example 47 per cent (Barber et al., 1962) and 84 per cent (Colcock, 1964). The reasons for this discrepancy are not immediately obvious, although clearly a more prolonged conservative policy prior to initial surgery, as practised by Garlock (1967), would offer one possible explanation.

In this series the incidence of local peritonism from ileal or ileocolic Crohn's disease sufficient to mimic acute appendicitis was 11 per cent, though some workers have found a higher proportion presenting in this fashion (Atwell et al., 1965).

Of all the patients requiring their initial surgery as an emergency procedure in the present series 83 per cent were found to have Crohn's disease confined to the small bowel, and the finding of unsuspected and otherwise uncomplicated regional enteritis may often have influenced the surgeon towards a conservative surgical management.

External fistulae in the present series occurred in 9 per cent of patients prior to the initial surgery at which the diagnosis of Crohn's disease was established, but in almost all cases followed upon drainage of a local intra-abdominal abscess. Indeed, apart from a greater incidence of external fistulas subsequent to initial surgery, there was a marked similarity in the pattern of indications for initial surgery and for subsequent readmissions (*Tables II, III*). This observation highlights the fact that surgery may only provide a temporary respite from exacerbations in a disease which has a natural tendency to chronicity and recurrence.

Turning to the surgical management of Crohn's disease, it is clear that most workers in the past decade have advocated resection (Barber et al., 1963; Letwin et al., 1963; Atwell et al., 1965; Colcock and Fortin, 1965; de Dombal et al., 1971a; Kyle, 1971). In all of these studies, as in the present series, the conclusions are open to criticism in that the studies were retrospective and the operative procedures were not randomly allocated in a prospective manner. However, in the Glasgow series it appeared that the surgeons had exercised a free choice of surgical procedures since the incidence of patients with extensive or complicated local disease in each surgical group was low. It would seem reasonable, therefore, to make some general observations and comparisons of the surgical procedures used in the Glasgow study.

The present series appears to have a high incidence of exploratory operations without definitive surgery. This has occurred because many of these operations were performed for diagnostic reasons, or the Crohn's disease was discovered either at an emergency operation for suspected appendicitis or during elective surgery for other abdominal conditions. In such situations the surgeon avoided definitive surgery in apparently uncomplicated disease in which spontaneous remission is not unknown. Thus, these cases might reasonably be considered to reflect the natural history of the disease. Indeed, the findings of the present series show that a proportion of patients do remain free from major symptoms (30 per cent), but this figure may be even lower with a more extended follow-up. Seventy per cent of patients undergoing exploratory operation as the sole procedure have therefore had a major recurrence of symptoms requiring admission to hospital, and 60 per cent have required further surgery. These findings accord well with the report by Edwards (1969) and may support a more aggressive approach to Crohn's disease discovered at laparotomy.

Bypass in continuity offers a simpler technical procedure although recurrence rates of between 40 and 92 per cent are quoted (Williams, 1971). This experience is borne out by the Glasgow study where 67 per cent of patients having an initial bypass in continuity required further admission on account of major recurrence of symptoms. Bypass with exclusion, a procedure relatively neglected in this series, has been advocated on the grounds of a lower recurrence rate. Although not without its own rare hazards of perforation associated with closed loop obstruction (Waye and Lithgoe, 1967; Steinberg et al., 1973a, b) and intussusception (Garlock, 1967), it does seem a procedure worthy of further evaluation.

Resection, on the other hand, has in this series been followed by the lowest recurrence rate (33 per cent), and this agrees well with the experience of other large series (37 per cent Colcock, 1964; 34 per cent de Dombal et al., 1971b). Recurrence is commoner after ileal disease (37 per cent) and ileocolic disease (34 per cent) than after large bowel disease alone (18 per cent), and this supports the findings of others (Marshak et al., 1966; de Dombal et al., 1971a). Examination of the recurrence rate following bypass surgery and purely exploratory procedures shows little difference. The question then arises as to whether bypass surgery alters the natural history of the disease or offers any respite from symptoms. Examination of the rate of recurrence up to 4 years after surgery clearly shows that the recurrence rate in the early period after bypass surgery is approximately half that seen following an exploratory procedure when small bowel disease (group 1) and ileocolic disease (group 2) are considered. In these groups of patients it is clear that bypass surgery does prolong the period of remission for a large number of patients. However, for patients with large bowel disease alone (group 3) no advantage was conferred by colostomy as the sole procedure, and this procedure should be reserved for obstructive lesions. On the other hand, the recurrence rate up to 4 years after resection is much lower in all three groups, but since recurrence is related to length of follow-up (Garlock et al., 1951; de Dombal et al., 1971b; Fielding et al., 1972), this procedure may only have postponed the occurrence of major symptoms for a considerable number of patients. The presence of distant skip lesions untouched but recognized at resection of the principal diseased segment may also adversely affect the results of excisional surgery. Nevertheless, on the basis of the 4-year postoperative results, it seems clear that resection offers the best prospects as regards risk of recurrence.

Any assessment of the relative merits of surgical procedures must of course be influenced by the postoperative morbidity and mortality. External fistulas after initial surgery occurred not uncommonly and in the present series provided the indication for readmission in 23 per cent of cases (19 per cent Schofield, 1965; 21 per cent Koutny, 1968; 19 per cent Edwards, 1969). Fistulation was more frequent after laparotomy (18 per cent) or bypass operation (12 per cent) where the diseased bowel remained *in situ* than after resection (3 per cent). The Birmingham series (Steinberg et al., 1973a, b) gave closely similar figures (19, 13 and 5 per cent respectively). In the Glasgow series there were, in addition to the 6 free perforations prior to initial surgery, 4 free perforations within 10 days of operation, none of which was adjacent to an anastomosis. Nevertheless, free anastomotic leakage occurred on 10 occasions in the series and all but one followed resection. With one exception, anastomotic leakage proved fatal.

The immediate postoperative mortality in the present series was 7·4 per cent, although the overall death rate from causes directly related to Crohn's disease was 9·9 per cent. This mortality rate is remarkably similar to that reported in other large European series. De Dombal (1972) reported an overall death rate from causes related to Crohn's disease of 11·3 per cent with a postoperative mortality of 7·2 per cent. Davis (1961) reported a 9 per cent death rate from causes related to Crohn's disease. While there may be an irreducible mortality for surgery in this disease, Kyle (1973) has suggested that 'proper and timely' resection may carry a mortality of only 2 per cent. It seems likely that incomplete resection of involved bowel may explain some of the 5 per cent of deaths following resection in the Glasgow series by making anastomotic leakage or perforation more likely, and this reflects the surgeon's difficulty in making a macroscopic assessment at operation of the extent of disease (Atwell et al., 1965). Furthermore, these postoperative problems may reflect the natural instinct of the surgeon in resecting to a minimal extent in a disorder where the likelihood of further surgery is high.

Indeed the tendency for the disease to extend or recur proved one of the prominent features of this study, and it is noteworthy that a large number of patients who initially had disease confined to the small bowel (group 1) later developed ileocolitis (group 2) due to progression of the disease. This tendency for extension to occur in an aboral manner has been previously noted for large bowel disease alone (Brahme and Wenckert, 1970), but so far has received little attention in small bowel disease.

Perhaps it is no longer the place of surgery in the management of Crohn's disease which requires evaluation but the timing of operation. As to which procedure is best, final proof may have to await prospectively planned studies.

Acknowledgements

We wish to thank the surgeons of the West of Scotland Surgical Association for permission to study the records of their patients. Thanks are also due to the record staffs of all the hospitals in the Glasgow region for help, to the Medical Illustrations Department of the Victoria Infirmary, Glasgow, for the figures and to Mrs Anne Whyte and Miss Patricia Leask, Victoria Infirmary, for secretarial help. Finally, we are most grateful to Sir Andrew Watt Kay, Regius Professor of Surgery, Western Infirmary, Glasgow, for helpful guidance in preparing the final manuscript.

Significance of faecoliths in the diagnosis of acute appendicitis

B. GILL AND R. E. CUDMORE*

SUMMARY

Three cases are presented which demonstrate the significance of faecoliths in the diagnosis of acute appendicitis in infants. A wide spectrum of symptoms is noteworthy. The usefulness of a plain X-ray of the abdomen in infants with acute abdomen is stressed.

ACUTE appendicitis is probably the most common surgical emergency encountered in a children's hospital. The diagnosis is usually made on clinical judgement alone because it is well known that ancillary investigation may be misleading. Routine radiography of the abdomen is rarely helpful except to indicate intestinal obstruction. In an ill infant, however, where the diagnosis of appendicitis may be uncertain, X-ray of the abdomen may show a faecolith. Should it do so, the diagnosis of appendicitis is certain.

Case reports

Case 1: M. M., an 8-week-old male infant was admitted to Alder Hey Children's Hospital, Liverpool, on 31 August 1973 with a history of refusing feeds, vomiting and mild upper respiratory infection for 3 days. He was febrile, lethargic, dehydrated and had slight abdominal distension and tenderness in the right iliac fossa. An erect X-ray of the abdomen showed multiple fluid levels and a faecolith in the right iliac fossa.

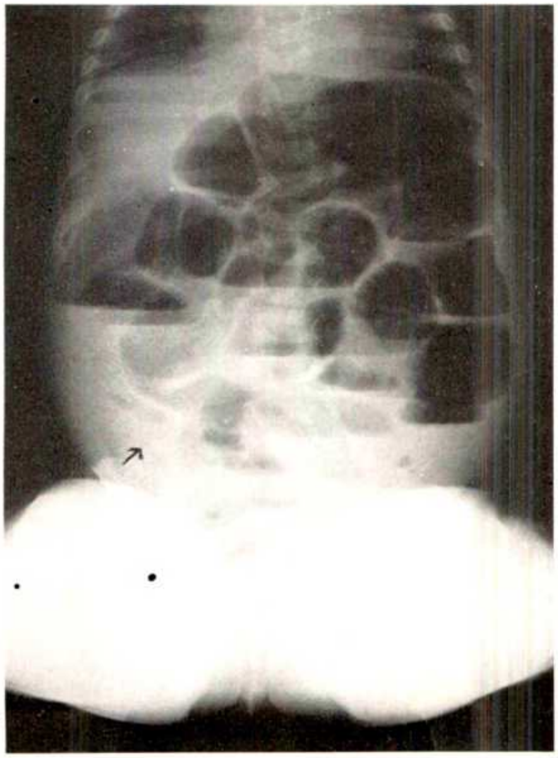

Fig. 1. *Case* 2. Erect film of the abdomen showing distended loops of small bowel with fluid levels and a round faecolith in the right iliac fossa.

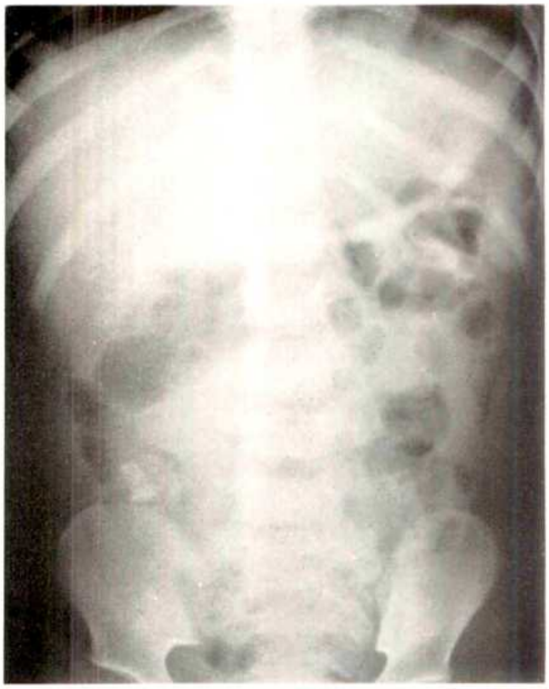

Fig. 2. *Case* 3. X-ray of the abdomen showing no evidence of obstruction, but a large rectangular faecolith in the right iliac fossa.

Through a right lower quadrant muscle-cutting incision a perforated gangrenous appendix was removed and the wound drained. Postoperatively he was treated with an intravenous infusion, gastric suction and wide spectrum antibiotics. Ten days later he developed right upper lobe collapse, which required a second course of antibiotics. He made good progress and was discharged after 4 weeks.

Case 2: C. D., a 21-month-old male was admitted on 31 October 1973 having been febrile, lethargic and refusing feeds for 4–5 days. There had been no diarrhoea or upper respiratory infection and he had vomited only once. He was a sick infant with a poor peripheral circulation. The most remarkable features were gross abdominal distension, oedema and tenderness on the right side of the abdomen and absent bowel sounds. An X-ray of the abdomen showed the features of an adynamic ileus and a faecolith in the right iliac fossa (*Fig.* 1).

After initial resuscitation with intravenous fluids and antibiotic therapy a perforated gangrenous appendix was removed. The faecolith lay free in the peritoneal cavity. The peritoneum

---

* Paediatric Surgical Unit, Alder Hey Children's Hospital, Liverpool.

was drained and the wound closed. Distension persisted for 3 days, followed by diarrhoea and spontaneous decompression. The wound dehisced on the tenth day and was resutured. Recovery after this was uneventful. He was discharged after 3 weeks.

Case 3: A. B., a 1-year-old female, was admitted on 26 March 1974, with a history of being generally unwell with anorexia, vomiting and fever for 48 hours. On admission her temperature was 39 °C. A proper physical examination required sedation with Vallergan. She was noted to have tenderness and guarding in the right iliac fossa and was reluctant to move her right leg. An erect film of the abdomen showed fluid levels and a large faecolith in the right iliac fossa (*Fig.* 2). A perforated gangrenous appendix was removed and the peritoneal cavity drained. Recovery was slow but uneventful. She was discharged after 3 weeks.

Discussion

Appendicitis in children under 2 years is very rare. Snyder and Chaffin (1952) and Wilkinson et al. (1969) reported an incidence of less than 2 per cent. Grosfield et al. (1973) discussed in great detail the clinical features, management and the pitfalls in the diagnosis of acute appendicitis in the first 2 years of life. Our 3 cases illustrate almost all the clinical signs described by them, with one additional common feature—that of a faecolith in the right iliac fossa, demonstrable on an erect X-ray film of the abdomen (*see Figs.* 1 and 2). Wilkinson et al. (1969) described the X-ray features in the diagnosis of appendicitis in infants and reported a faecolith in 33 per cent of his cases. Grosfield et al. (1973) reported an incidence of 28 per cent which is much higher than the 10 per cent reported in older children and the 7 per cent in adults (Brooks and Killen, 1965).

Appendicitis, for all its masquerading in the early years of life, should be considered a curable condition. There has been a tremendous reduction in mortality, but it is still as high as 6·7 per cent (Fields and Cole, 1967) and 9·3 per cent (Crosfield et al., 1973), presumably because of a high perforation rate due to late diagnosis.

From the above results one concludes that in this age group a plain X-ray of abdomen should form an essential part of the investigation of the sick infant with possible abdominal pathology. Where a faecolith is shown the diagnosis is certain and early exploration is mandatory.

Addendum

Since this article was submitted for publication there have been a further 3 cases with similar clinical and radiographic findings who were shown to have appendicitis.

Nolvadex–a more acceptable approach to breast cancer treatment

Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

The changing pattern of hospital admissions for diverticular disease of the colon

JAMES KYLE AND ALAN I. DAVIDSON*

SUMMARY

Hospital admissions for symptomatic diverticular disease of the colon were studied during two periods, 1958–61 and 1968–71, in a relatively closed community in north-east Scotland. There was a significant increase in the numbers admitted, from 206 to 366. In the earlier 4-year period among patients aged 70 years and over there was a preponderance of females, but in the later study period the risk of developing symptomatic disease was almost as great among elderly males. Most of the elderly female patients were widowed city dwellers. The proportion of patients requiring operation for or dying from diverticular disease declined, but perforation remained as a frequent complication carrying a high mortality.

In the early years of this century diverticular disease of the colon was rare (Keith, 1910). At that time males were affected more often than females. The male to female ratio in Leeds was 2 : 1 (Telling and Gruner, 1917). The introduction of barium enema examinations (de Quervain, 1914; Spriggs and Marxer, 1927) made recognition easier, and the diagnosis of diverticular disease was made more frequently. The symptomatic forms of the disease are known to be very much commoner in Europeans than in Africans, Asians or Melanesians (Wells, 1949; Kyle et al., 1967; Painter and Burkitt, 1971). However, no detailed investigation has been conducted in a relatively static European community to ascertain whether or not there has been any change in the numbers of patients with troublesome disease who require to be admitted to hospital, or any alteration in the severity of the disease and the need for surgical intervention. The present study was undertaken in order to provide this information.

The north-east of Scotland is a region particularly suitable for this type of comparative study. Geographically, it is relatively isolated from the rest of Scotland, its hospital services are centralized in Aberdeen and until the end of 1971 there had been very little change in the population of the region.

Patients and methods

Records were obtained of all the patients in north-east Scotland who required admission to hospital because of symptomatic colonic diverticular disease during two study periods 10 years apart. The periods were each of 4 years' duration, from 1958 to 1961 and from 1968 to 1971 respectively. The same methods of ascertainment and evaluation, and the same diagnostic criteria were used throughout the two periods. The population figures were based on the 1961 and 1971 censuses (Registrar General, 1963, 1973), which showed that the population of the area had fallen from 393 801 to 389 610.

Ascertainment

Since 1955 all general hospital records in the area have been centralized, being coded and stored in the Records Department of the Royal Infirmary, Aberdeen. Retrieval of records from this department has proved to be remarkably accurate (Kyle, 1971), and the Records Department provided the case sheets of all the patients admitted during the study periods. In addition, all morbid anatomy in the area is carried out in the University Department of Pathology, which supplied information about resected specimens and autopsies on patients with diverticular disease.

Diagnostic criteria

Only patients having colonic diverticular disease as their principal reason for admission to hospital were accepted. The presence of diverticula was confirmed by barium enema, by operation or at autopsy in every case. In addition each patient had at least two of the following clinical features: (*a*) left-sided or lower abdominal pain; (*b*) deep tenderness in the left iliac fossa; (*c*) altered bowel habit; (*d*) rectal bleeding; (*e*) pyrexia over 37·5 °C; (*f*) leucocytosis of 10 000/mm^3 (10^9/l) or more.

Geographical limits

The patients were permanently resident within the city of Aberdeen and the counties of Aberdeenshire, Banff and Kincardine. The three hospitals where diverticular disease is investigated and treated are all in Aberdeen. Some suburban districts, market towns and fishing ports are included with the mainly rural areas of the counties.

Exclusions

1. Patients in whom diverticular disease was an incidental finding; these were mostly long stay geriatric patients with other serious illnesses.
2. Solitary diverticulum of the caecum, which may be congenital.
3. Unexplained rectal bleeding where diverticula had not been convincingly demonstrated.

The number of hospital patients of each sex and the corresponding admission rates were calculated, and the change between the two study periods was then

50–69	1·06	0·85
70–89	0·51	0·85

analysed statistically. The incidence of major complications, the need for elective surgery and the mortality for the two 4-year periods were compared.

Results

Hospital admissions

During the first period, 1958–61, 206 patients with colonic diverticular disease were admitted to hospital, compared with 366 in the second period, 1968–71 (*Table I*). The annual hospital admission rates per 100 000 population were, therefore, 12·8 and 23·5 respectively.

The age of the patients in the two periods was very similar, ranging from 35 to 89 years in the first period and from 32 to 95 years in the second. No case was encountered in the first three decades of life, and the population at risk was aged 30 years and above. *Table II* shows this population broken down into 20-year age groups. Between 1968 and 1971 there were 2 males and 5 females aged 90 years or more. These are excluded from *Tables III* and *IV*, which show the numbers of male and of female patients in each of three 20-year age groups admitted in the two study periods, together with the corresponding hospital admission rates per 100 000 of the population at risk. The increases in the admission rates between 1958–61 and 1968–71 are given. Apart from middle-aged males, the increases in cases admitted were statistically significant at the 5 per cent level for the three age groups of both sexes.

Between 1958 and 1961 there were 74 males and 132 females, while for 1968–71 the corresponding figures were 139 and 227 respectively. The totals for both sexes increased between the two periods, but the increase was proportionately greater for males than for females. In the earlier study there was a male preponderance of nearly 3 : 2 in the 30–49 age group, but a 2 : 1 female preponderance beyond the age of 70 years. In the second study this marked swing with advancing years had vanished, the male to female ratio approximating to 1 : 1 for each of the three 20-year age groups (*Table V*).

Elective operations

Table VI shows the number of elective operations performed. Staged elective procedures have been counted as single operations. Although the number of patients admitted had increased by almost 80 per cent, the actual numbers of operations considered necessary were almost identical in the two periods. Consequently, the percentage of patients coming to operation in 1968–71 declined.

Complications

Colovesical fistula is perhaps the most dramatic complication of colonic diverticular disease. The number of cases noted was 5 in the first period and 4 in the second. However, perforation is potentially the most lethal complication. The number of colonic perforations rose from 18 in the 1958–61 period to 28 in 1968–71, an increase that closely parallels that in the hospital admissions for diverticular disease. The mortality rate for perforation also rose from 28 to 39 per cent.

Mortality

Twenty-five patients (7 male, 18 female) in the first period and 26 patients (9 male, 17 female) in the second study period died as a direct result of their diverticular condition. The mortality rate fell from 12·1 to 7·1 per cent.

Discussion

The distinction formerly made between 'diverticulosis' and 'diverticulitis' has been abandoned. Resected specimens of colon from patients who clinically appeared to have had diverticulitis may not show any evidence of inflammation on histological examination (Morson, 1963). Radiological appearances which at one time were considered to be helpful in differentiating diverticulosis from diverticulitis are now known to be unreliable (Parks et al., 1970). Consequently, the term 'diverticular disease of the colon' is preferred. In the present investigation all the patients were having symptoms from their disease, the symptoms being judged sufficiently severe to merit admission to hospital. This has not been the case in previously published series, many of which contained both inpatients and outpatients. Diagnostic criteria frequently were different or were not stated and often geographical limits and the size of the populations at risk were undefined. Direct comparison of the present results with those from earlier series is therefore impossible. The Aberdeen hospital admissions for the two study periods 10 years apart have simply been compared with each other. All the patients in the area rely on the hospitals in Aberdeen for medical services, and no patients go to other centres for treatment.

Elective operations are undertaken only after careful consideration, and it was felt that comparison of the numbers performed in the two periods might be relevant. By contrast, emergency procedures are employed for so many different complications that analysis would not be meaningful. Only two clear-cut and unmistakable complications, perforation and colovesical fistula, have been studied. Other complications such as obstruction (Bolt, 1973) and rectal haemorrhage (Heald and Ray, 1971) have many possible causes and may vary greatly in severity, and consequently they have not been considered.

The marked increase in hospital admissions in the Aberdeen area during a decade is statistically significant. Does it represent a true change in the incidence of diverticular disease in a community that was relatively closed until the end of 1971? The criteria for acceptance into each of the two study groups were applied uniformly by the same observers. The proportion of case records rejected was very similar on both occasions—131 excluded and 206 accepted for the 1958–61 period, 261 excluded and 366 accepted for 1968–71. The exclusions mostly were cases where either the diagnosis was presumptive but not proved or the demonstrated diverticula of colon were considered to be incidental findings, not responsible for admission to hospital. The diagnostic methods in use were identical throughout; colonoscopy was not used before 1971. The increase in hospital admissions therefore seems genuine, but this increase in the hospital admission rate for severe disease does not necessarily mean that the incidence of colonic diverticula in the population at risk has also risen. However, from the surgeon's point of view the admission rate is the best guide that is available as to how common potentially troublesome diverticula are in the community. It is clearly impractical to subject large numbers of apparently normal people to repeated barium enema examinations.

There may be several explanations for the larger numbers admitted, apart from a true increase in incidence. First, the level of diagnostic activity may have risen, particularly with regard to radiological investigation. It is true that the number of barium enema examinations carried out at Aberdeen Royal Infirmary rose from 892 in 1960 to 1800 in 1971, although this need not imply that twice as many patients with diverticula in their colons were found. Fifteen years ago patients with real bowel symptoms and abdominal pain almost certainly would have had a barium enema. In more recent times, contrast examinations may frequently have been requested in order to exclude a somewhat unlikely lesion rather than in the reasonable expectation of finding it. Only 20–25 per cent of patients in whom diverticular disease is demonstrated need to come into hospital. An independent radiological survey in this area (Petrie et al., 1972) for the 4 years 1967–70 revealed 1567 cases with major diverticula formation in the colon, but in 1968–71 only 366 patients required admission. A similar observation has been made in New York (Gennaro and Rosemond, 1974). Part of the increase in the number of barium enemas could well be due to more patients really developing diverticula and requiring X-ray, even if the proportion admitted remained constant.

A second possible explanation for the increased number of hospital cases is that the criteria for admission have changed. A patient in genuine distress would have been admitted at once in any of the years studied, but it is possible that with an ageing population in recent years more elderly people were admitted for investigation rather than for active treatment. About 40 per cent of patients with colonic diverticular disease have other major associated illnesses (Kyle, 1968), and during 1968–71 some patients in this category may have been admitted for a few nights rather than having a barium enema performed as an outpatient. It seems likely that there has been a slight but important change in the surgeon's indications for ordering a barium enema and in the decision as to whether it should be performed on an inpatient or an outpatient basis.

An increase in the age of the population could contribute to the larger number of inpatients with diverticular disease. The older a person is, the more likely is he or she to have diverticula (Manousos et al., 1967). Above the age of 70 years about 40 per cent of the population have the condition; at this stage of life asymptomatic diverticula should probably be regarded as a variant of the normal rather than a pathological abnormality. Between 1961 and 1971 there was an 11 per cent increase in the population group aged between 70 and 89 years, the increase being nearly twice as great for females (2053) as for males (1211). Clearly, if 40 per cent of these additional elderly citizens developed diverticula, and if 20 per cent of those so affected required admission to hospital, the extra 160 patients in 1968–71 are readily accounted for. Unfortunately, this simple theory does not explain the disproportionate rise in the number of

Table VI: ELECTIVE OPERATIONS FOR COLONIC DIVERTICULAR DISEASE

Date	Male No.	Male %	Female No.	Female %
1958–61	13 (74)	18	18 (132)	4
1968–71	16 (139)	12	18 (227)	9

Numbers in parentheses are the total numbers of patients of each sex for the study period.

male patients in the second study period, when the population change showed twice as many additional females as males in the 70–89-year age group. Nevertheless, the gradual ageing of the population at risk must be a major factor in accounting for the observed changes in the admission rates for diverticular disease in north-east Scotland.

The similarity in the numbers of elective operations and of deaths in the two study periods might suggest that indeed the pattern of diverticular disease had not changed, and that only the willingness to admit to hospital had altered. However, between the two study periods very important changes in treatment were introduced. In 1964 Painter advocated the high residue diet for medical treatment, and Reilly described the operation of colomyotomy. The high residue diet has been of great value in clinical practice and could well account for the observed reduction in the percentage of patients requiring operation shown in *Table VI*. Mortality expressed as a percentage of the total number of cases might also be expected to fall with better methods of treatment. It is not considered that the actual numbers of operations and deaths indicate that the numbers admitted are falsely high.

Colovesical fistula is probably the outcome of severe and long-standing diverticular disease. With improved medical treatment the chances of any individual patient developing this complication should be reduced, and this appeared to be true in 1968–71. The complication which increased markedly was perforation into the peritoneal cavity. The number of perforations rose by 61 per cent between 1958–61 and 1968–71; this percentage increase was broadly similar to that for admissions (77 per cent), and so tends to support the accuracy of the latter figure. Certainly the diagnosis of perforation was not being made too readily in the second study period—the mortality for perforation rose from 28 per cent to a disconcerting 39 per cent. Perhaps too much reliance should not be placed on the rising number of perforations of the colon, because in diverticular disease it may behave in maverick fashion, sometimes striking out of the blue and occasionally affecting younger subjects.

There is no ready explanation for the changing sex pattern in diverticular disease of the colon. The findings in the earlier part of this investigation are in agreement with those reported from Belfast (Parks, 1969), a slight excess of males below 50 years of age changing to a marked excess of female patients aged over 70 years. In the second part of the present investigation the chances of a male in any of the three 20-year age groups at risk developing symptomatic disease were almost as great as for a female. In studying the 1968–71 case records it became apparent that a disproportionately large number of the females lived in the City of Aberdeen—128 out of 227 (56·4 per cent) compared with 54 out of 139 males (39·2 per cent). Only 46·7 per cent of the total population of the area reside within the city. Among the female city patients 83 (61·2 per cent) were 70 years of age or over, the majority being widowed; 24 male city patients (44·4 per cent) were in this age group. However, diverticula do not develop overnight, and the place of residence at the time of admission is much less important than the place where the patient spent the major part of his or her life.

The nature of haemorrhoids*

W. H. F. THOMSON†

SUMMARY

An anatomical and clinical study aimed at uncovering factors likely to be helpful in understanding the true nature of haemorrhoids is described. The main finding was of specialized 'cushions' of submucosal tissue lining the anal canal; it is argued that piles are merely the result of their displacement.

THE theory that haemorrhoids result from varicosity of the anal submucosal veins, although currently orthodox, is not the only one available nor has it always been the most popular. In the past century, in fact, most European authorities considered piles to be caused by some sort of vascular tissue hyperplasia—a concept which recent work in Germany seems to support. Another theory suggests that piles are caused simply by a downward displacement of the anal canal lining. The three theories will now be reviewed.

The varicose vein theory

Dating from the time of Galen and Hippocrates (Parks, 1955), this theory probably stems from the observation of discrete dilatations on the course of the veins within the tissues of a haemorrhoid—John Hunter noticed them in a specimen that he dissected and clearly thought them to be the cause of haemorrhoids (Hunterian Museum (1848) *Descriptive Catalogue*).

The dilatations being thought of as the basic pathological change, various explanations were put forward to account for their development. There are two main groups: (1) explanations incriminating a localized increase in venous pressure, and (2) explanations incriminating a localized weakness in the vein wall.

The various mechanisms suggested as bringing about an increase in venous pressure are based on certain anatomical observations; the absence of valves in the portal vein and its tributaries, and the degree and site of the communications between the portal and systemic circulations in the anal canal. Morgagni (1749) introduced the idea that localization of the 'varices' to the anus might be attributable to the upright posture of man (the effect of the hydrostatic pressure resulting from an uninterrupted column of blood), and agreed with Boerhaave that the increased intra-abdominal pressure of straining would be transmitted to the anal veins. Verneuil (1855b), after injecting and dissecting the superior rectal vein and failing to find communications between it and the systemic circulation, suggested that the dilatations might be the result of obstruction to the venous return at the point where he had found the veins to pass through unprotected muscular 'button-holes' in the rectal wall (he thought the success of forcible dilatation of the anus—which he had introduced empirically in the treatment of piles—to be due to stretching of the 'button-holes' (Allingham and Allingham, 1896). Duret (1877) made similar dissections but discovered communications between the two systems traversing the anal sphincter. He therefore thought the fault lay in venous obstruction due to anal sphincter spasm and suggested a mechanism whereby the venous return upwards would also be cut off during defaecation.

Because none of the ideas of Morgagni, Verneuil or Duret seemed to explain the curious localization of the 'varices' to the lower half of the anal canal, Parks (1956) and later Graham-Stewart (1963) put forward alternative theories (although based on Duret's description of the anatomy) which seemed more adequately to fit the facts. However, free communications between the portal and systemic circulations in the anal canal have been demonstrated by Cruveilheir (1867), Konstantinowitch (1872), Quénu (1892) and Tuttle (1906) and so the concept that a localized increase in venous pressure is to blame in haemorrhoids is based on uncertain anatomical evidence.

Quénu, recognizing the lack of an anatomical mechanism to mediate a local increase in venous pressure, suggested that the fault lay in a weakness in the vein wall. He suggested that the venous dilatations, which he called 'haemorrhoids in miniature' (Quénu and Hartmann, 1895; *Fig.* 1), might be a manifestation of vein wall destruction brought about by recurrent infections resulting from repeated minor trauma at defaecation. He recognized, however, that there was little histological evidence to back up his ideas and his theory was never generally accepted. Recently, in fact, Jackson and Robertson (1965) reported that they had found no evidence of past or current infection in the haemorrhoidectomy specimens they had examined over the course of 2 years.

From this brief history the varicose vein theory can be seen to depend upon the observation of venous dilatations in the tissues of piles. However, Sappey (1874), Duret (1877) and Waldeyer (1899) have all reported finding dilatations on the course of the anal canal veins in children, suggesting that they are normal structures.

The vascular hyperplasia theory

Popular in the nineteenth century—Malgaigne (1837), Velpeau (1826), Bourgery (1840) and Cruveilhier (1852) considering piles to result from a sort of erectile tissue metaplasia, and Virchow (1863) and Allingham (1973) considering them to be haemangiomatous in nature—this theory probably arose out of the observed similarity between the tissues of a pile and cavernous tissue (Hunter, 1728–1793).

* The subject of a thesis accepted by London University for a Master of Surgery degree, 1974.

† Southampton General Hospital. Present address: Gloucester Royal Hospital.

The special nature of the anal submucosa, which Bourgery (1840) likened to an 'erectile web' and which Treitz (1853) noticed to be extraordinarily thick, was considered by Stieve (1928) to function as part of the anal continence mechanism by contributing to anal closure. Staubesand et al. (1963) demonstrated arteriovenous communications in the anal submucosa which seemed to them to indicate that the anal submucosa (which they also likened to cavernous tissue and called the 'corpus cavernosum recti') might have erectile properties; if so it would enhance, they believed, its capacity to fulfil its supposed function. Their observations stimulated them and Stelzner (1963) to suggest that piles might result from hyperplasia of the 'corpus cavernosum recti'. They cited in support the bright red colour of the bleeding (explicable, if coming from the venous spaces, on the basis of the existence of arteriovenous communications) and the fact that the bleeding of piles is said to be their earliest manifestation.

The sliding anal lining theory

Gass and Adams (1950) considered piles to result from degeneration of supportive tissue in the anal canal because of their observation, in 200 haemorrhoidectomy specimens, of fragmentation of connective tissue, and their belief that haemorrhoids were associated with a lax anus. Hughes (1957) and Patey (1972) supported the idea because it fitted the appearance of piles.

Of relevance is the existence in the anal submucosa of a substantial layer of smooth muscle. It was first described by Treitz (1853), who noted that it arose partly from the internal sphincter and partly, by passing through the internal sphincter, from the conjoined longitudinal muscle. He described it as passing downwards in the anal submucosa to form a supporting scaffold around the veins of the haemorrhoidal venous plexus and as making a significant contribution to the bulk of the columns of Morgagni. He considered it to function in preventing prolapse of the bulky tissues of the anal lining. Kohlrausch (1854), in describing it, expressed a similar view and called it the 'sustentator tunicae mucosae'. Ellis also discovered it in 1854 (Ellis and Ford, 1867) and, ignorant of the other two reports, called it the 'corrugator cutis ani'. Béraud (1858) next reported it, and later still, Roux (1881). Finally, it was described by Fine and Lawes (1940) who called it the 'muscularis submucosi ani'. For the sake of brevity and in recognition of his original discovery it will be called here 'Treitz's muscle'. Despite its repeated documentation it has yet to find a proper place in modern textbooks of anatomy.

The following investigation was undertaken in order to examine the premisses upon which the three hypotheses are based.

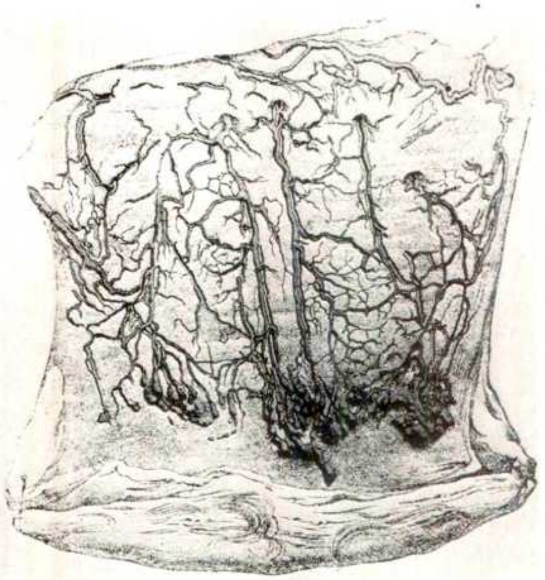

Fig. 1. Diagram from Quénu and Hartmann's (1895) *Chirurgie du Rectum*, showing the haemorrhoidal venous plexus after injection and dissection. The appearance of the venous dilatations, which they thought to be pathological, seems to have given rise to the term 'bunches of grapes' in connection with haemorrhoids.

Materials and methods

The study was partly anatomical and partly clinical.

The anatomical study

Ninety-five cadaveric anorectal specimens (obtained by pelvic exenteration *en bloc* with the anal canal from 10 infants, 3 adolescents and 82 adults) were prepared and dissected. Proctoscopy, with photography to provide a record, was carried out in 42 patients without haemorrhoids.

Demonstration of the arterial system: Fifty adult specimens were used. Each was prepared by injecting the superior rectal artery with latex and slitting the specimen open in the anterior midline. The entire extrarectal and submucosal course of the superior, middle and inferior rectal arteries (the parts incorporated in the specimen) was then dissected and a diagram made from each dissection.

Demonstration of the venous system: Fifty adult, 3 adolescent and 10 infant specimens were used. In 25 of the adult specimens the superior rectal vein was injected with a barium sulphate suspension and the specimen was slit open anteriorly and X-rayed. In the other 25 latex was injected and the venous system was dissected.

The 10 infant and 3 adolescent specimens were prepared in a different way. First, the superior rectal vein was cannulated and injected retrogradely with diluted ammoniated latex (Tompsett, 1970)—before removal of the specimen in order to facilitate cannulation (manipulation during removal usually empties the vein, which in infants then becomes invisible). Next the specimen was removed and the anorectum was slit open anteriorly. The anal canal lining, in

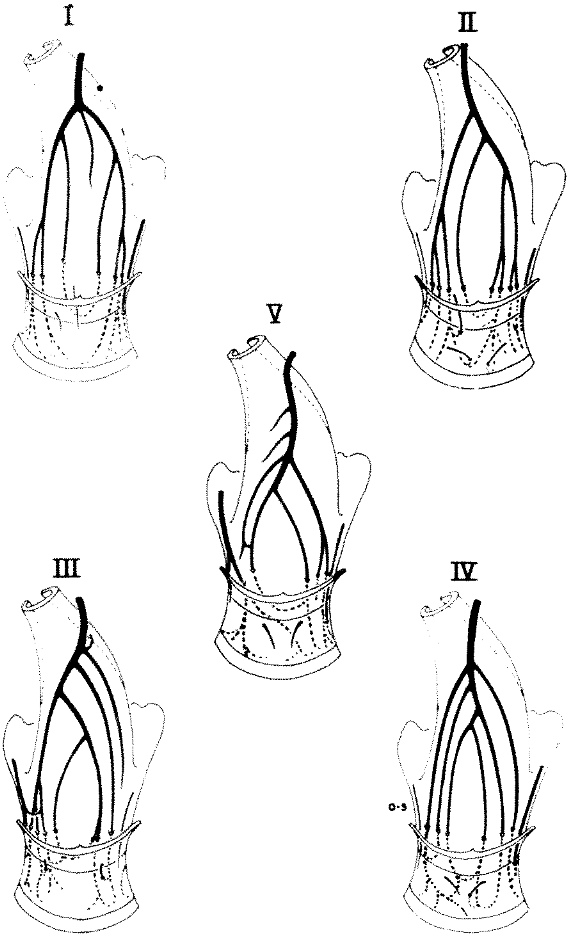

Fig. 2. Diagrams of the posterior aspect of dissected anorectal specimens showing five different patterns of arterial supply. The extrarectal course is represented by a continuous line and the submucosal by a dotted one. The middle rectal arteries can be seen joining the specimens anterolaterally above the levatores ani, and the inferior rectal vessels below the muscle, mainly posteromedially.

continuity with a cuff of perianal skin, was then dissected off the internal sphincter and subcutaneous part of the external sphincter and pinned out in formalin. After fixation it was rendered translucent by Spalteholz's technique (Culling, 1963) and studied under the dissecting microscope.

Demonstration of the arteriovenous communications: An anorectal specimen removed from the corpse of a young man soon after death was prepared. Infusion with saline through cannulae in both the superior rectal artery and vein enabled all severed vessels to be detected and sealed and the vascular tree to be cleared of blood. On completion (when perfusion of the superior rectal artery resulted in an almost clear flow from the vein) simultaneous infusion of the artery and vein was carried out using diluted ammoniated and filtered latex at constant pressure (red latex at 200 mm Hg and blue latex at 80 mm Hg respectively). The anal canal lining was then removed, rendered translucent as before and studied under the dissecting microscope.

Demonstration of Treitz's muscle: Treitz's muscle was demonstrated both macroscopically and microscopically. It was seen with the naked eye on raising the flap of anal lining as described above. Thirty-five specimens, slit open anteriorly, were dissected in the following manner; the perianal skin was dissected off the ischiorectal fat and external sphincter and, working cephalad, off the lowermost part of the internal sphincter; the muscle was then seen as a continuous layer of longitudinally running fibres on the deep surface of the flap. Further dissection showed it to arise circumferentially from the deep surface of the internal sphincter in almost discrete bundles which passed downwards into the anal submucosa and which had to be divided in order to elevate the flap. The appearance was recorded photographically.

For its microscopic demonstration longitudinal and transverse sections were made of the anal canal. In order to demonstrate its relationship to the venous plexus the veins were first distended by injecting the superior rectal vein with a mixture of barium sulphate and 4 per cent gelatin.

Demonstration of the anal 'cushions': This term, introduced for the first time, is used here to describe cushions of submucosal tissue in the anal canal. They were first observed during the proctoscopic examination of 42 consecutive patients with neither symptoms nor signs of haemorrhoids, and subsequently demonstrated in the anatomical preparations. The completely dissected flap of anal canal lining described above was merely held up to the light; discrete masses of thickened submucosa could then be clearly seen. They were demonstrated in 35 consecutive specimens—25 from adults and 10 from infants. Prior injection of the venous plexus made the cushions more obvious.

Proctoscopic examination of normal controls was carried out in the hope that it might provide information to explain the regular appearance of piles in the right anterior, right posterior and left lateral positions in the anal canal (Goodsall and Miles, 1900). It became clear that the anal lumen was not a simple anteroposterior slit as usually described (Phillips and Edwards, 1965) but a basically triradiate one. The appearance of the anal lumen in 42 normal patients was recorded photographically.

The clinical study

Eighty consecutive patients admitted to Southampton General Hospital for the surgical treatment of their prolapsing piles were asked which of their symptoms had started first, the bleeding or the prolapse. At operation the position and appearance of the piles were recorded by colour photography. The haemorrhoidectomy specimens were studied histologically.

Results

The anatomical study

The arterial system: Miles (1919) wrote that the branching pattern of the superior rectal artery was constant, being characterized by a bifurcation of the

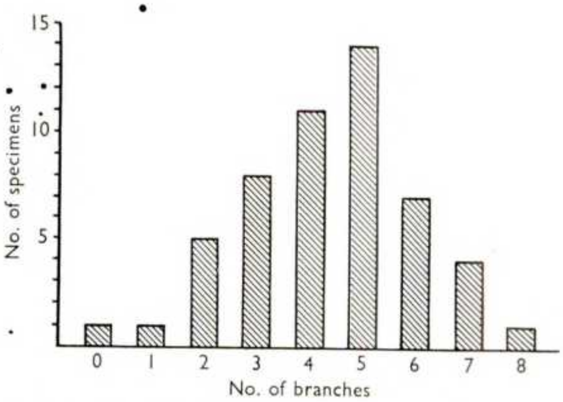

Fig. 3. Number of branches of the superior rectal artery reaching the haemorrhoidal zone.

main trunk into right and left branches with the right branch then producing anterior and posterior divisions while the left remained substantially single. He stated that it thereby determined the position of piles around the anal circumference (accounting for their regular appearance in the right anterior, right posterior and left lateral positions)—piles being said to be due to varicosity of the radicles of the superior rectal vein which, he said, followed the branches of the artery. However, Miles's description would not have been applicable to any of the 50 specimens which the present author has dissected, despite there being a wide variety of branching patterns amongst them (*Fig.* 2). In 23 specimens (46 per cent) the pattern was found to conform to the orthodox description (Warwick and Williams, 1973), the main trunk birfurcating to produce right and left divisions which then divided into a variable number of branches supplying the ipsilateral side of the rectum and anal canal; in the other 27 specimens various patterns were found. In some the main trunk passed to the right, giving off branches to the left, in others it passed to the left, supplying branches to the right, and in another group there was a trifurcation of the main trunk. The trifurcation group was also not uniform since the central component behaved in a number of different ways—supplying branches to both sides of the anal canal in some, to one side only in others and in yet others not reaching the anal canal, supplying only the rectum. Furthermore, the arrangement of the branches as they pierced the wall of the rectum to pass down into the anal submucosa was found to be unrelated to the primary branching pattern of the superior rectal artery; it was not unusual, in fact, to find a large primary branch being spent entirely in the supply of the rectum, not reaching the anal submucosa at all.

An average of five branches of the superior rectal artery was found actually to reach the haemorrhoidal zone (*Fig.* 3). However, in 35 specimens (70 per cent) substantial branches of one or both middle rectal arteries could also be traced into the anal submucosa, and in 21 specimens (42 per cent) the inferior haemorrhoidal arteries were found to make a similar contribution.

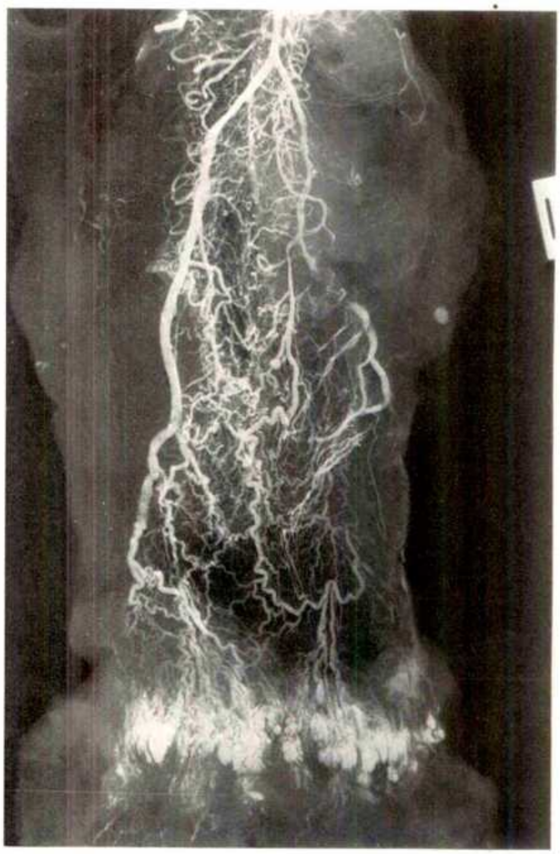

Fig. 4. X-ray of an opened-out anorectal specimen in which the superior rectal vein has been injected with a barium sulphate suspension. There was no evidence of piles; in other specimens where gross pile formations were present the radiographic appearance was the same.

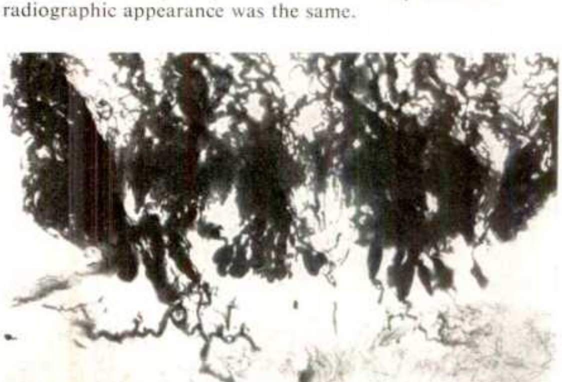

Fig. 5. Adult anorectal specimen prepared by latex injection of the superior rectal vein, followed by Spalteholz's procedure to render the tissues translucent; specimen slit open anteriorly.

In 5 specimens (10 per cent) an interesting and previously undescribed vascular anomaly was encountered, the middle rectal artery usurping, in the supply of the anal canal, part (and in 1 specimen, all) of the function of the superior rectal artery. Instead of piercing the muscle wall low down anteriorly as is usual (below the attachment of the levator ani at the

Fig. 6. Anorectal specimens from a full-term neonate (*a*) and a 3-month old infant (*b*). The superior rectal vein had been injected with coloured latex and the tissues cleared by Spalteholz's technique.

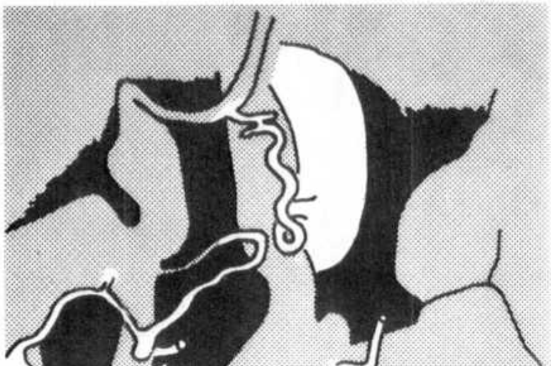

Fig. 7. A projection drawing of the arteriovenous communications in the anal submucosa; arteries white, veins stippled.

anorectal junction), the middle rectal artery pierced the rectal wall anterolaterally 3–4 cm above the levatores ani—where the superior rectal artery normally traverses the muscle wall. It then ran down into the anal submucosa to supply whole segments of it in place of the superior rectal; in the case of the specimen referred to in parentheses above the entire anal submucosa was supplied by the two middle rectal arteries.

In summary the anal lining derives a rich blood supply from the superior, middle and inferior rectal arteries, whose branches reach the anal submucosa in a most varied way.

The venous system—venous dilatations: Each of the 50 adult specimens exhibited discrete dilatations on the course of the veins of the anal submucosal venous plexus. A typical X-ray is illustrated in *Fig.* 4 and the typical appearance of a latex-injected specimen is shown in *Fig.* 5. The dilatations may be fusiform, saccular or serpiginous and are confined to the lower half of the anal canal. Above the pectinate line they occur in greatest profusion and complexity, but a second series—fewer in number and with a tendency to be larger in size—occurs below it. In 3 specimens thrombosis (confirmed histologically) had occurred recently in a dilatation below the pectinate line; the appearance was the same as that known as 'perianal haematoma'.

Of the 10 infant specimens, venous dilatations were found in 8 (*Fig.* 6). The 2 specimens in which they were absent were obtained from the bodies of very small stillbirths.

The venous system—portosystemic communications: Free communications both below and through the anal sphincter were demonstrated between the tributaries of the superior, middle and inferior rectal veins in all 25 specimens in which dissection was possible (the ones in which the veins had been injected with latex). They were also seen in all 25 specimens where radiography was employed (*see Fig.* 4), although the two-dimensional limitations of the X-rays precluded determination of their exact course. The communicating veins passing below the anal sphincter to join the subcutaneous tributaries of the inferior rectal vein were seen in all the specimens in which the anal canal lining had been removed and rendered translucent (*see Figs.* 5, 6).

Arteriovenous communications: In the specimen prepared for their demonstration red latex from the arterial side was seen under the dissecting microscope to have filled some of the venous dilatations by way of tiny direct arteriovenous communications. Because they wound through different planes it was not possible to demonstrate them photographically. A few dissected ones were sketched using the drawing attachment on a Wild Stereo-Zoom dissecting microscope; a drawing is illustrated in *Fig.* 7.

Treitz's muscle: Easily found in all 35 specimens, Treitz's muscle was seen to emerge from the internal sphincter at different levels in almost discrete, overlapping bands (*Fig.* 8). The bands passed downwards into the anal submucosa to form a continuous sheet on the deep surface of the submucosa from the pectinate line downwards. Microscopy demonstrated it to arise partly from the internal sphincter itself—the circular fibres of which seemed to curve inwards and downwards to form it—and partly from the conjoined longitudinal muscle, the contributing fibres passing between the imbricated fasciculi of the internal sphincter.

It was found to be distributed in three ways: to form a network around the haemorrhoidal venous plexus, to fan out into the perianal skin and to rejoin the longitudinal muscle (either around the lower border of the internal sphincter or through its lowermost fasciculus). It was found to contain a considerable amount of elastic tissue and to be hypertrophied, sometimes markedly so, in specimens exhibiting prolapsing haemorrhoids.

The anal 'cushions': As a result of the proctoscopic examination of patients with neither the symptoms nor signs of piles, the anal lumen was observed to form a more or less triradiate slit (*Fig*. 9). The stem of the 'Y' so formed was found invariably to approach the midline posteriorly, with its arms embracing a pad of tissue anteriorly or, more usually, in the right anterior position. The three folds thus separated three pads of tissue, the anal 'cushions', lying in the left lateral, right anterior and right posterior positions. Secondary folds were found to intersect the cushions to a variable degree. The anatomical dissections (*Fig*. 10) demonstrated the cushions to be caused by thickenings in the submucosa, and histology showed them to be composed largely of blood vessels (the venous dilatations making the main contribution), smooth muscle (Treitz's muscle) and elastic and connective tissue.

The columns of Morgagni are produced by longitudinal clefts in the anal cushions. With little doubt they represent the mechanism whereby the cushions are able to adapt to the large changes in size of the anal lumen. Their relationship to the anal cushions can only be seen properly in specimens in which the haemorrhoidal venous plexus has been filled.

The clinical study

Order of appearance of symptoms: The results from questioning 66 patients with prolapsing piles are displayed in *Fig*. 11. The majority of patients (60 per cent) claimed that prolapse had been the first symptom. Only 8 patients (12 per cent) thought that bleeding had started first, of whom one had a coexistent rectal polyp, one had anal fissure and a third gave an unreliable history, being mentally retarded. In only 5 patients, therefore, did it seem certain that the first manifestation of piles had been bleeding.

Histology of haemorrhoidectomy specimens: Twenty-five haemorrhoidectomy specimens were examined. They showed a stroma of connective tissue containing many blood vessels, and interweaving bundles of smooth muscle. Large vascular spaces were found to a greater or lesser extent in all the specimens, but apart from exhibiting evidence of recent or past thrombosis they were similar to the ones seen in the anal submucosa of cadaveric specimens in which there was no evidence of piles. There was no sign of vascular hyperplasia.

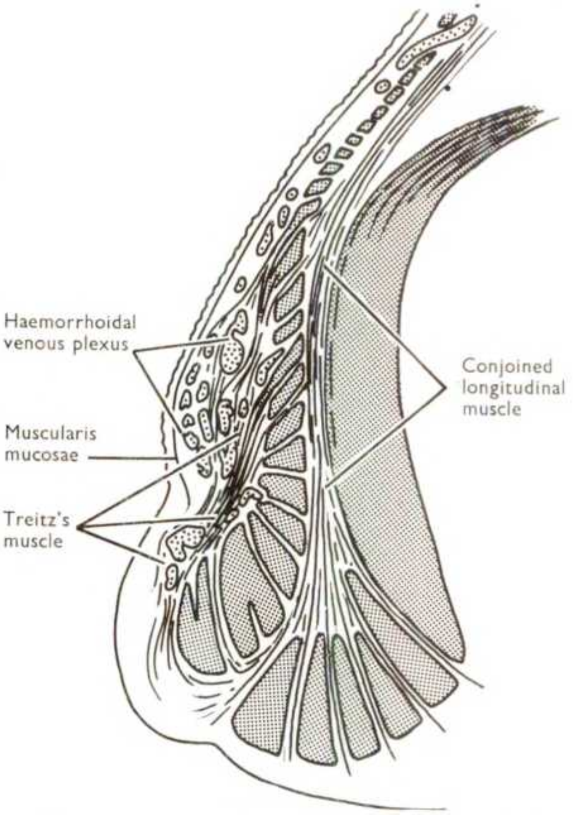

Fig. 8. A composite diagram of Treitz's muscle derived from longitudinal sections of the anal canal.

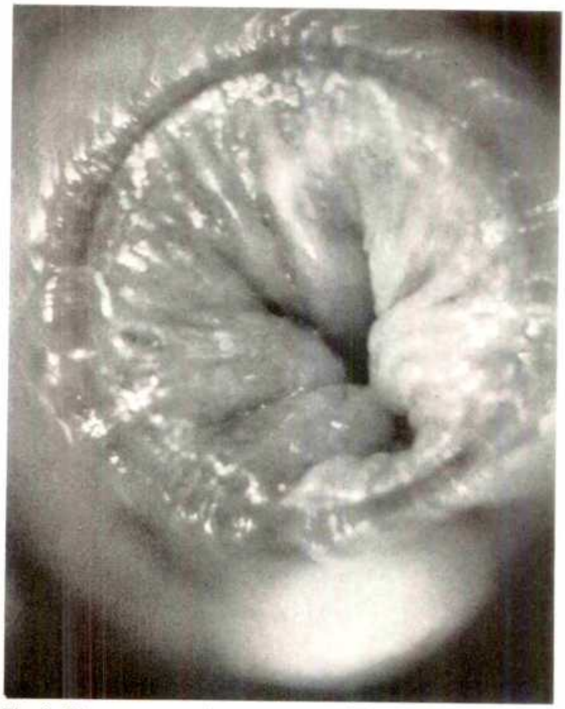

Fig. 9. The proctoscopic appearance of the anal 'cushions' in a normal individual. The triradiate configuration of the anal lumen is well shown.

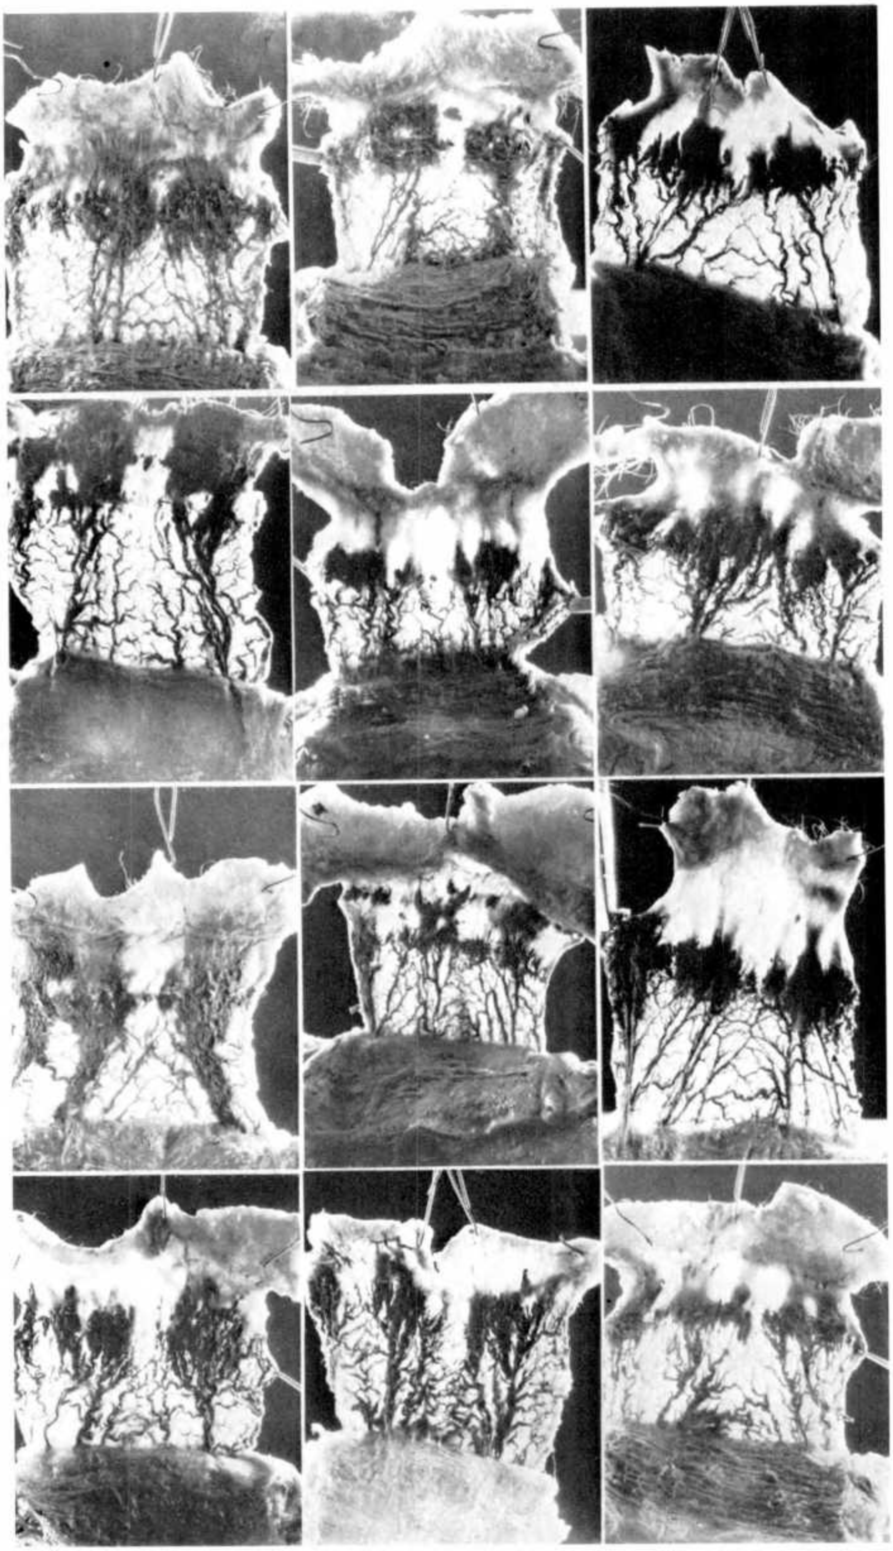

Fig. 10. Twelve anorectal specimens in which the anal lining has been dissected up and viewed with transmitted light. The arrangement of the anal cushions is similar.

The large vascular spaces were found to be deep in the substance of the pile, separated from the surface not only by connective tissue but by the muscularis mucosae. Many piles were noticed to have a red granular mucosa which histology revealed to be due to a rich network of dilated capillaries in the lamina propria (between the mucosal epithelium and the muscularis mucosae). Bleeding from these capillaries was clearly seen in some sections.

Discussion

The arterial system

Konstantinovitch (1872), Quénu (1893) and Widmer (1955) made dissections of the superior rectal artery; no other reports of personal dissections have been found in the literature. The present author's findings concerning its course and distribution are similar to theirs. None of them reported an arrangement similar to that described by Miles (1919), and Miles does not disclose the source of his information. No evidence from the author's dissections or from those reported by others supports his contention that the branching pattern of the superior rectal artery is responsible for the position of piles around the anal circumference.

The venous system

The present study has confirmed the observations of Sappey (1874), Duret (1877) and Waldeyer (1899) that the dilatations of the veins of the haemorrhoidal venous plexus are constant and normal structures, being present from birth and being found in all adults. Quénu (1892) seems to be the only one to have looked for them in children in vain. His failure was undoubtedly due to his technique—he was unable to cannulate the superior rectal vein in children because of its smallness and therefore could not inject it.

The findings of Cruveilhier (1867), Konstantinovitch (1872), Quénu (1892) and Tuttle (1906) concerning the abundance of communications between the portal and systemic circulations both below and through the anal sphincter have also been confirmed. The fact that Verneuil (1855a) was unable to find any at all and that Duret (1877) only found the ones passing through the sphincter is presumably attributable to technique.

Arteriovenous communications

Direct arteriovenous communications in the anal submucosa have been demonstrated by serial section (Stelzner et al., 1962) and by radiography (Schmidt and Staubesand, 1972) and now using the latex-injected preparation described here. As suggested by Staubesand et al. (1963), the anal submucosa may have an erectile property and the arteriovenous communications may function in the erectile mechanism. The enormous blood supply that the anal submucosa receives—greatly in excess of the conceivable metabolic requirements of its constituent cells—is further evidence for the existence of such a mechanism.

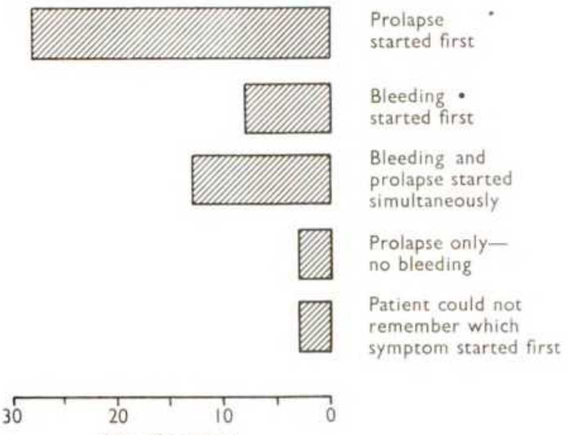

Fig. 11. The chronological order of appearance of symptoms in 66 patients admitted for treatment of prolapsing piles.

Treitz's muscle

As described by Treitz (1853), the haemorrhoidal venous plexus was found to be supported by a scaffold of smooth muscle and elastic tissue which was found to arise partly from the internal sphincter and partly from the conjoined longitudinal muscle. Both Treitz (1853) and Kohlrausch (1854) thought its function to be the support of the anal lining during defaecation. In view of the bulkiness of the anal lining (due to the anal cushions) and the strategic arrangement of the muscle their opinion is probably correct.

The anal cushions

Bourgery (1839) observed the anal lining to form a bolster, and Treitz (1853) also commented on its thickness. Stieve (1928) noted that it shared this characteristic with the mucosal lining of various other orifices in the body and suggested that its function was to assist in anal closure. As Staubesand et al. (1963) pointed out, an erectile mechanism would greatly enhance such a property.

The present study has shown that the submucosa does not form a continuous ring of thickened tissue in the anal canal but a discontinuous series of cushions, the three main ones being found constantly in the left lateral, right anterior and right posterior positions. Treitz (1853) also referred to cushions of tissue in the anal lining and noted that the submucosal smooth muscle contributes a great deal to their bulk. In the present study the haemorrhoidal venous plexus was found to be congregated within the cushions as well, not forming a uniform network around the anal canal. The dilatations of the veins obviously enable the cushions to vary considerably in size.

The segregation of the submucosal pad into separate cushions seems an ideal arrangement for adapting the anal canal lining to great changes in size of the lumen. The importance of the cushions may be judged from the fact that they are formed early on in embryonic life, as the illustrations in Johnson's (1914) paper on the development of the anorectum testify.

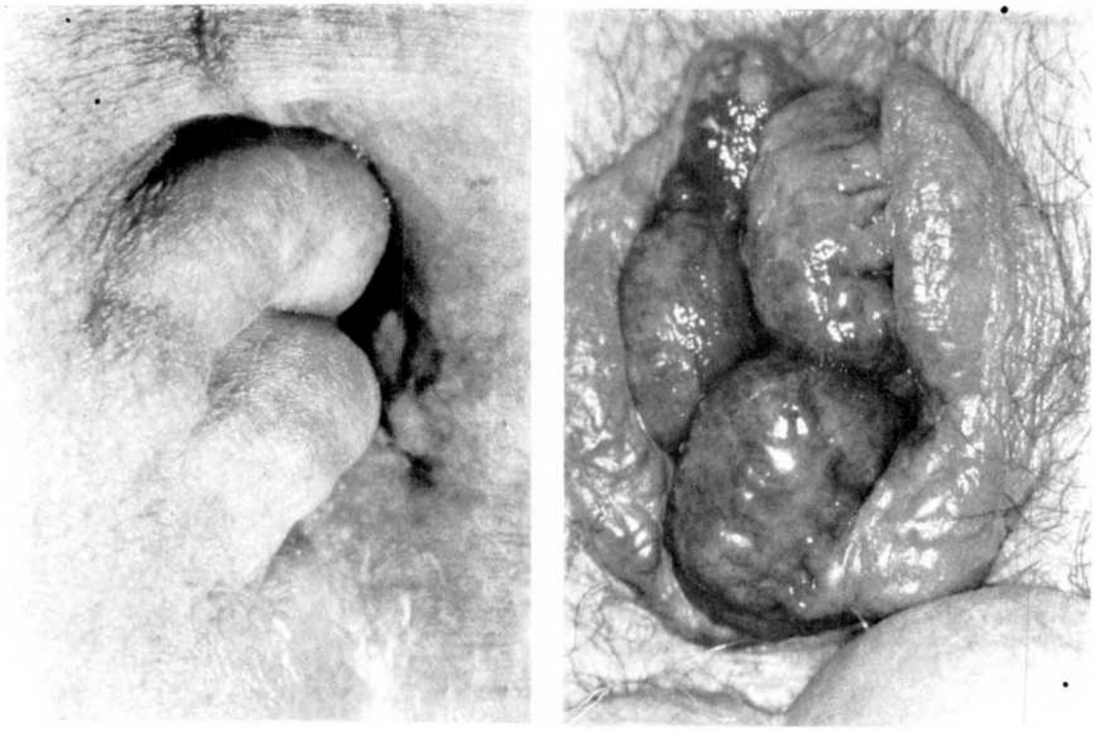

Fig. 12. *a*, Anal varices in a patient with portal hypertension due to cirrhosis of the liver. *b*, Prolapsed piles.

What are haemorrhoids?

The varicose vein theory: Stemming from the assumption that the dilatations of the veins of the internal rectal venous plexus are the result of a pathological change, the varicose vein theory is shown to be invalid by the confirmation that the dilatations are in fact normal. Furthermore, there is no evidence of a restriction of venous drainage from the anus or of a high venous pressure developing there. The fact that piles are no more common in patients with portal hypertension than in the population at large (Hunt, 1958) is additional evidence against the theory, as is the fact that when anal varices occur as the result of portal hypertension (a rare event) the appearance is quite different from that of haemorrhoids (*Fig.* 12). The varicose vein theory also fails to account for the fact that piles are frequently single and more common in the right anterior position than elsewhere (Goodsall and Miles, 1900).

The vascular hyperplasia theory: The present histological studies, like those of Graham-Stewart (1962), suggest that haemorrhoidal bleeding comes not from the venous spaces ('arterialized' by direct communications or not) but from dilated capillaries in the lamina propria. Furthermore, although dramatic descriptions of haemorrhage are often given, only 1 patient in the present study was anaemic at the time of admission, and Graham-Stewart found only 1 patient to be anaemic in his series of 150 haemorrhoid sufferers.

Although it is generally taught that bleeding is the first manifestation of piles (Gabriel, 1963; Goligher, 1967), there appears to have been no study, apart from the present one, which has been aimed at examining this dictum. The present findings suggest that bleeding is usually the later symptom and probably secondary to prolapse.

There is, therefore, neither histological nor circumstantial evidence to support the vascular hyperplasia theory.

The sliding anal lining theory: The discovery of the anal canal to be lined by specialized highly vascular cushions of submucosal tissue provides substantial support for the sliding anal lining theory. It would account for the regular appearance of piles in the right anterior, right posterior and left lateral positions and for their naked eye and histological appearances. Accepting that the cushions contribute to the mechanism of anal closure, it accounts for the high percentage of people who experience an impairment of continence after haemorrhoidectomy (Bennett et al., 1963). The triradiate configuration of the anal lumen due to the cushions might also explain the conflicting measurements of anal force as differently estimated by means of a force gauge and a balloon (Collins et al., 1967). That piles have been found to be associated with straining and an irregular bowel habit (Hyams and Philpott, 1970) is also compatible with the sliding anal lining theory. An irregular bowel habit is likely to be associated with hard and bulky stools, causing straining, which would be more likely to push the cushions out of the anal canal. Furthermore, straining, by producing a general increase in venous pressure, may cause engorgement of the cushions during defaecation, making their displacement more likely. Treitz's muscle might become stretched and disrupted if repeatedly subjected to such forces, intermittent and then permanent prolapse of the cushions resulting. Perhaps the right anterior cushion is subjected to a greater downward force during defaecation than the others, accounting for its more frequent prolapse.

Anal compliance may also be a factor in the production of haemorrhoids and may be associated with diet and stool consistency, accounting for the geographical distribution of the condition (Burkitt, 1972). If the anal canal is narrow and relatively rigid the cushions would be more likely to be pushed out on defaecation (perhaps helping to explain the success reported for forcible anal dilatation (Sames, 1972) in the treatment of piles).

Once prolapsed, the venous drainage from a haemorrhoid may be impeded by anal closure on the superior and middle rectal tributaries and by kinking of the inferior ones. The pile (displaced anal 'cushion') would then become engorged and therefore more difficult to replace. Such a situation may predispose to thrombosis—an 'attack of the piles'.

The success accorded to injection (Goligher, 1967) and banding (Barron, 1963) in the treatment of prolapsing piles is probably attributable to fibrosis in the cushion and a reduction in its size respectively.

In summary, the available evidence suggests that the theory that piles are nothing more than a sliding downwards of part of the anal canal lining is probably the correct one.

Acknowledgements

I would like to thank Mr T. Rowntree, Mr J. D. Jenkins, Dr J. Guthrie and the staff of the Morbid Anatomy Department, Southampton, Professor Sir James Fraser and the Wessex Regional Health Authority; without their help and encouragement this work could never have been undertaken.

The pick of the bunch for skin disinfection

'Dispray' 1 Quick Prep.
(formerly known as Hibispray 1)
is an ideal preparation for skin and
hand disinfection in the busy
hospital environment.
At the touch of a button it gives
fast, easy and economical
skin disinfection prior to surgery,
injection or venepuncture.
When colour delineation
is required eg. pre-operatively,
'Dispray' 3 is available
with a red dye.

The 'Dispray' range
combines effectiveness with
convenience and economy.

Instant Availability.
No solutions to prepare.

Easy to use.
No swabs or bottles required.

Quick and Effective.
Rapid bactericidal action.

Efficient Application.
No wasted solutions.

Contents cannot
be contaminated.
No rejected solutions.

Long Lasting.
Contents of one can treat 100 sq. ft.

Localization of parathyroid adenomas by computer-assisted parathyroid scanning

P. J. ELL, A. TODD-POKROPEK AND K. E. BRITTON*

SUMMARY

In an attempt to localize adenomas of the parathyroid glands 36 patients with suspected hyperparathyroidism were studied with a computer-assisted double isotope scanning technique. Six patients were excluded from the statistical analysis because of uninterpretable scans. A definite localization was made with the computer-assisted scan in 16 patients. In 14 of these patients the site of the tumours was correctly predicted. In 14 patients no localization was seen on the scan. Four of these patients were classified as false negatives.

In 14 out of the 16 correctly localized tumours two-thirds had weights equal to or less than 1·5 g.

A NON-INVASIVE technique is required for localizing parathyroid adenomas before surgery since generally no diagnosis can be made on clinical grounds as to the side and site of the lesion. The most accurate method currently available for the localization of parathyroid adenomas is by radio-immunoassay of parathyroid hormone in samples obtained by direct venous catheterization (O'Riordan et al., 1971; Powell et al., 1972; Auerbach et al., 1973; Eisenberg et al., 1974). Although a considerable improvement over the previous techniques, it still suffers from being an invasive method, a lengthy procedure in time and requiring the administration of an average of 100 g of iodide to the patient.

Traditional scanning procedures using ^{75}Se selenomethionine have proved to be unsatisfactory in localizing functioning adenomas of the parathyroid glands (Garrow and Smith, 1968; Di Giulio and Beierwaltes, 1968; McGeown et al., 1968), particularly if these are below 2 g in weight. Diffuse hyperplastic glands also escape visualization (Di Giulio and Morales, 1969; Keeling and Todd-Pokropek, 1969). Part of the difficulty with these procedures may lie in the fact that the thyroid also takes up ^{75}Se selenomethionine. To overcome this problem a technique of subtracting a ^{125}I iodide thyroid scan from the ^{75}Se selenomethionine thyroid plus parathyroid scan has been devised.

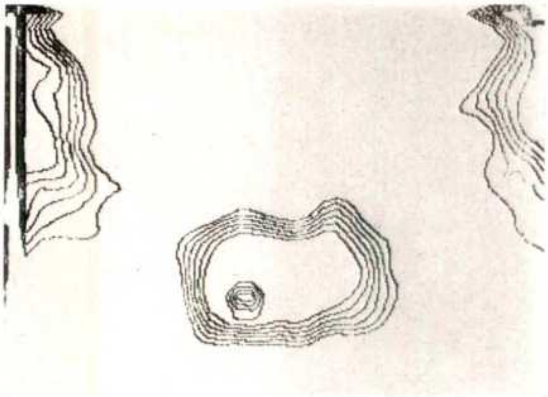

Fig. 1. A right inferior lesion is evident within the thyroid contour.

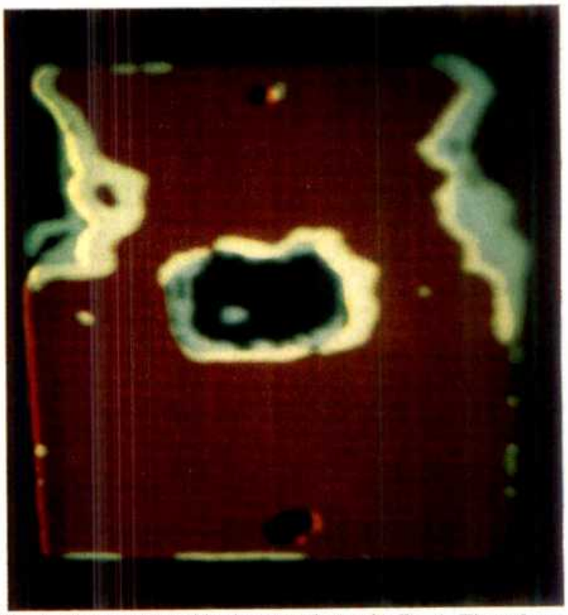

Fig. 2. The parathyroid adenoma shown in *Fig.* 1. The colour bands represent different levels of count rate.

Methods

Each patient receives 100 μCi ^{125}I sodium iodide orally 24 hours before and 250 μCi ^{75}Se selenomethionine intravenously 15 minutes before scanning the neck using the upper detector of a Selo DS4/45 double-headed scanner. The scan takes 20 minutes. The data on the distribution of each isotope are recorded separately at 3-mm intervals and registered by a two-channel punched paper tape system. The paper tape is then read into the departmental Varian 620i computer system. The data are manipulated by a scan analysis program. Two matrices are created for the two radionuclide distributions. Each point in a matrix corresponds to a point in the scan of the neck. The value at a point in the matrix represents the count density at that point in the scan. The 'peak

count' of a matrix is chosen as that position at which the sum of the counts within a 3 × 3 element area is a maximum. A scaling factor is determined as the ratio of the 'peak count' in the iodide scan matrix and the equivalent point in the selenomethionine scan matrix. The thyroid scan matrix is then subtracted, element by element, from the scaled-up matrix of the thyroid plus parathyroid scan. To reduce the effect of count rate fluctuations, the resulting image undergoes a 9-point smoothing procedure. The image is then interpretable, but of low contrast. An interactive colour television display is used to determine the appropriate levels of background subtraction and contrast enhancement. The final hard copy output is either as a contour map provided by an electrostatic plotter (*Fig.* 1) or recently as an SX70 colour Polaroid print of the television display (*Fig.* 2).

	1·5			1·1	
Inferior	3·5	1·0		1·5	1·5
	1·3	1·3	3·0	1·4	1·0

Results

This study concerns a series of 36 patients with suspected hyperparathyroidism (*Table I*), none of whom had an abnormal palpable mass in the neck. Useful information was obtained from the routine unprocessed scan in only 4 cases. The results of computer-assisted scanning were compared with the data obtained from surgical exploration of the neck and clinical follow-up (*Table II*). Six patients with uninterpretable scans were excluded from the statistical analysis.

A definite localization was made with the computer-assisted parathyroid scan in 16 patients. In 14 of these the site of the tumour was correctly predicted. In the remaining 14 patients no evidence of focal increase of the ^{75}Se selenomethionine was seen on the scan. Of these, 4 were classified after operation and follow-up as false negatives. From 14 out of the 16 tumours which were correctly localized on the scan

10 had weights equal or below 1·5 g; the remaining tumours had weights between 1·6 and 3·5 g.

The false negatives included 1 case of diffuse hyperplasia and 3 cases of parathyroid adenoma. Two of these adenomas (*Cases* 13 and 33) were situated retrosternally and would be obscured as a result of uptake of selenomethionine by normal bone marrow, and the third was only 0·2 g in weight (*Case* 29). The anatomical sites of the correctly diagnosed tumours and the distribution of their weights are shown in *Table III*.

Two false positive scans were reported: 1 patient was not explored surgically and at follow-up no longer demonstrated hypercalcaemia; the other recovered from a persistently raised calcium level after a negative surgical exploration of the neck.

The 6 cases excluded from statistical analysis because of equivocal scans included 2 cases of hyperplasia (*Cases* 12 and 14), 2 cases with negative surgical exploration of the neck with recovery from raised serum calcium levels (*Cases* 16 and 20) and 2 cases of right inferior parathyroid adenoma (*Cases* 3 and 22), weighing 0·25 and 1·5 g respectively.

Discussion

The concept of subtracting an image of the thyroid from the composite thyroid plus parathyroid image is similar in principle to the usual method of pancreas scanning. The subtraction method highlights areas of increased selenomethionine concentration that are to be expected in parathyroid adenomas. The images are handled by an interactive computer system in order to make best possible use of the data.

The disadvantages of the technique are twofold: its dependence on the correct working of a sophisticated computer system and the problem of selenomethionine uptake by bone marrow. A midline concentration of activity due to the seventh cervical vertebra is usual and the retrosternal region is not accessible. A subtraction technique utilizing a bone-marrow-seeking agent, such as ^{111}In indium chloride, might circumvent this problem.

The advantages of the technique are its non-invasive nature, short investigation time and direct display on a two-dimensional map of the relation of the suspected adenoma to the thyroid gland. In this retrospective series approximately two-thirds of the correctly predicted tumours had weights equal to or less than 1·5 g.

Facilities for computer-assisted analysis of scan data are becoming generally available in regional centres for nuclear medicine. The place of computer-assisted parathyroid scanning is likely to be after a clear clinical and biochemical diagnosis of hyperparathyroidism has been made—a criterion not met in some patients in this pilot series due to lack of unequivocal biochemical confirmation of hyperparathyroidism. It appears that if definite localization is made by computer-assisted parathyroid scanning, then there may be less need for parathyroid venous sampling. An equivocal or negative result should not be relied upon. At present a comparison with the venous sampling technique is being attempted. This presents difficulties because if the venous sampling technique is performed after the scan the samples are contaminated with ^{75}Se selenomethionine, and if the venous sampling is before the scan the high iodide contrast media prevent an adequate thyroid scan. Substitution of ^{99}Tc^{m} pertechnetate for ^{125}I iodide has been partly successful in obtaining adequate thyroid scans in this situation. However, since the vascularity of some parathyroid adenomas may cause apparent uptake of pertechnetate (Arkles, 1974), this form of thyroid subtraction technique appears less reliable. A prospective study of computer-assisted parathyroid scanning using the technique described here is in progress. We hope these results will encourage others to re-evaluate the place of an advanced method of parathyroid scanning in locating preoperatively parathyroid adenomas.

Acknowledgements

We would like to thank Dr D. H. Keeling and Mr N. J. G. Brown for their help, Professor E. S. Williams for his interest and the consultants of many hospitals who referred patients for this study.

True recurrence of hyperparathyroidism: proposed criteria of recurrence

H. MULLER*

SUMMARY

Although recurrent hyperparathyroidism should not be rare on theoretical grounds, only a few cases of proved recurrence have been reported in the literature. In the present author's series only 4 patients (1 per cent) had true recurrence. Criteria for recurrence were:

1. Histological identification by biopsy and frozen section of all the parathyroid glands at the first operation.

2. Complete removal of the enlarged gland(s).

3. A normocalcaemic period of at least 1 year.

4. The finding of a tumour at the site of a previously normal-sized gland.

The low incidence of recurrent hyperparathyroidism might be explained by the long period of time needed for the recurrence to develop. However, since diagnosis of hyperparathyroidism is now more easily made and patients are treated surgically earlier in the course of the disease, the incidence of true recurrence might be expected to rise. A meticulous exploration during operation and careful follow-up of the patients are therefore required.

IN the past three decades many articles have appeared on the diagnosis, pathophysiology and treatment of primary hyperparathyroidism. However, there are very few publications on the long term results of surgical treatment. It is difficult to obtain sufficient data on the percentage of patients with persistent or recurrent hypercalcaemia after a 'successful' operation, and very few articles give an indication of the incidence (Cope et al., 1961; Hellström, 1965; McGeown, 1965). Recent developments in pathophysiology and histology of parathyroid tumours make these data desirable. In earlier publications the incidence of hyperplasia of all the parathyroid glands or the occurrence of multiple tumours was reported to be low. However, after Cope et al. (1958) published an article on chief cell hyperplasia, others started to report the condition frequently. The present author's experience in over 400 patients confirms this and he is inclined to the view that hyperplasia is the main cause of hyperparathyroidism. Biopsies taken from enlarged and from normal-sized glands often show nodular hyperplasia, and this makes it impossible for the pathologist to conclude which of the biopsies is taken from the so-called 'adenoma'. This finding is in complete agreement with the opinion of Paloyan et al. (1973), who stated: 'The entire spectrum of adenoma, hyperplasia, transitional cells, and normal histology may present not only in a single patient, but in some instances in a single gland.' In view of this, it is not surprising that they found multiple gland involvement in 65 per cent of their patients. In many of the author's patients also one 'adenoma', two normal-sized glands and one slightly enlarged gland weighing 80–90 mg (twice the normal weight) were found, and yet histological examination of biopsies of all the glands showed nodular hyperplasia. Since many surgeons would remove only the evidently enlarged gland a recurrence of hyperparathyroidism could be expected in similar cases.

There are other reasons for suspecting that hyperparathyroidism may recur. It is well known that hyperparathyroidism occurs predominantly in postmenopausal women (Muller, 1969), a group of patients in whom osteoporosis and a slightly elevated serum calcium are frequent. This indicates that hyperparathyroidism could be a secondary reaction in these patients and that recurrence after removal of an enlarged gland could be expected theoretically. The role of vitamin D, and especially of 1,25-dihydrocholecalciferol in this aspect may be important. If parathormone is a trophic hormone for the production of 1,25-dihydrocholecalciferol (Rasmussen, 1972), there might well be some sort of feedback mechanism which could provide the stimulus for hyperparathyroidism.

Why are more and more cases with hyperplasia of all the parathyroid glands found early in the course of the disease? This is conspicuous if early publications, mostly of cases with long standing disease, are compared with recent investigations using screening methods (Hellström, 1965; Cope, 1966; Haff, 1971; Paloyan et al., 1973). Bruining (1971) suggested that an unknown stimulus causes hyperplasia of all the glands with outgrowth of one gland eventually suppressing the other glands, but this unknown stimulus could also cause recurrence years after removal of the 'primary' tumour. In some patients with familial hyperparathyroidism or multiple endocrine adenopathy, only one enlarged parathyroid is found, while other patients are found to have hyperplasia of all four glands. If the one enlarged gland is removed, it is conceivable that the primary stimulus remains, eventually causing recurrence.

In this context it seemed of interest to review the literature and a personal series of patients to determine the incidence of recurrent hyperparathyroidism. In order to do this, it is necessary to define 'recurrence' and 'persistent hypercalcaemia'. At operation a tumour can be left behind erroneously after removal of

one or more 'adenomas'. The postoperative serum calcium levels will usually fall to normal or subnormal levels for some time, only to reach abnormally high levels again, often within a few weeks. If the patient is discharged from hospital in a relatively short time without adequate follow-up and is then readmitted because of recurrent clinical symptoms, a faulty diagnosis of recurrent, instead of persistent, hyperparathyroidism can be made. This happens only too often, especially when the surgeon is in the habit of terminating the operation when a large 'adenoma' is found, being afraid of damaging the other, presumably 'hypoplastic', parathyroids (Cope, 1966). In the author's experience the other parathyroids may be in a state of hypofunction, but are certainly not hypoplastic. The concept of 'recurrence' should be applied only to cases in which a previously normal-sized parathyroid has become a tumour. A true recurrence should therefore meet the following criteria:

1. All the glands are identified at the first operation and confirmed by biopsy and frozen section.
2. The enlarged glands are removed completely.
3. The patient has been normocalcaemic for at least a year since operation.
4. At reoperation a tumour is found at the site of a previously normal-sized gland.

Most reports fail to satisfy these strict criteria. In the excellent review of Norris (1947) of 322 cases no recurrences were mentioned, but at that time operative treatment of hyperparathyroidism had not been practised for long. Some of the published recurrences have been called carcinomas (Black and Ackerman, 1950; Kleinfeld, 1959; Ellis et al., 1971; Hill et al., 1972), but the differentiation of carcinoma from adenoma or even hyperplasia can be very difficult. Furthermore, the incidence of metastasizing carcinoma is very low. This makes it probable that many of the 'carcinomas' in reality are hyperplasias or adenomas. In the present series of over 400 cases no carcinoma was encountered, although the histology sometimes showed very 'wild' pictures with extensive areas of polymorphic cells. This confirms Dent's (1966) statement: 'The parathyroid gland appears to offer a unique opportunity for the study of tumour formation mechanisms, all stages from normal, through hyperplasia, to adenoma and finally cancer being readily available.' In some cases the recurrence stems from parts of the original benign tumour, intentionally or inadvertently left behind (Burk, 1947; Black and Ackerman, 1950; Keminger, 1964). It is regrettable that only a few authors describe the condition of the parathyroid glands not removed at operation (Greenfield et al., 1959; Haff et al., 1971; Clark and Taylor, 1972; Doury et al., 1973). Data about systematic biopsies with frozen section of all the glands are nearly always absent. In some papers on recurrent hyperparathyroidism (Shallow and Fry, 1948; Watanabe et al., 1961; Rienhoff et al., 1968; Fulmer et al., 1969; Cryer and Kissane, 1973) no search for the normal parathyroids was mentioned and no biopsies were taken for frozen section. Goldman et al. (1971) even warn against biopsy of normal glands since this might cause parathyroid infarction.

Perusal of the literature thus shows insufficient data on recurrent hyperparathyroidism and it seems very hazardous to advise subtotal parathyroidectomy as a routine procedure (Paloyan et al., 1969; Haff et al., 1971; Marsden and Day, 1973) solely on theoretical grounds. This might result in an unnecessarily high percentage of cases with persistent hypocalcaemia (Bruining, 1971). The present series of patients seemed well suited for a study of persistent and recurrent hyperparathyroidism, since the series is rather large and nearly all the patients were operated on by the same surgeon and the same routine was used throughout. Moreover an efficient follow-up in a small country like Holland is more feasible than in most other countries.

Observations

Of 394 patients, 62 were considered for further analysis, the other 332 patients having remained normocalcaemic since operation. Of these 62 patients, 46 were referred to the University Hospital Dijkzigt, Rotterdam, for reoperation after a negative exploration elsewhere or because of persistent hypercalcaemia in spite of removal of one or more tumours. An analysis of this group showed the following causes for hypercalcaemia: negative exploration(s) 44, other overlooked tumours 14 and true recurrences 4. Details of the 4 patients with time of recurrence are given below.

Case reports

Case 1: A woman, born in 1907, had had recurrent renal stones since 1945. In 1955 a diagnosis of hyperparathyroidism was made. At operation in June 1955 all four parathyroids were found and identified by biopsy and frozen section. The enlarged right lower parathyroid was removed (2·25 g). The other glands were normal. The patient was seen at regular intervals and in 1962 the serum calcium was still normal. Subsequently, the serum calcium rose to 11·5 mg/100 ml, and after clinical evaluation a further operation was performed (January 1964). Both upper parathyroids were enlarged and were therefore removed; each weighed approximately 200 mg. The remaining left lower parathyroid was normal. The patient has remained normocalcaemic.

Case 2: A woman, born in 1894, had had recurrent renal stones since 1953 with severe hypercalcaemia. A diagnosis of hyperparathyroidism was made and an operation followed (September 1955). The right upper, left upper and left lower glands were enlarged, the right lower one being normal. Biopsies of all the glands showed hyperplasia and the three enlarged glands were removed; they weighed 250, 500 and 600 mg respectively. Throughout 1964 the patient remained normocalcaemic. In 1967 hypercalcaemia was noted without any clinical manifestation of hyperparathyroidism. In view of her age she was treated with phosphate. She died in hospital in 1974 at the age of 80, and at autopsy a very large right lower parathyroid was found.

Case 3: A woman, born in 1916, had had recurrent renal stones since 1948. In 1956 severe hypercalcaemia was found and a diagnosis of hyperparathyroidism was made. At operation (October 1956) all four parathyroids were identified histologically by biopsy and frozen section. Only the enlarged left upper gland was removed (900 mg), the other three glands being of normal size. The serum calcium remained normal throughout 1964. From 1964 until 1972 serum calcium levels fluctuated between 10·7 and 11·7 mg/100 ml. A further operation was performed and a slightly enlarged left lower parathyroid was removed (September 1972). Since then she has remained normocalcaemic.

Case 4: A woman, born in 1924, had had recurrent attacks of cystopyelitis and general malaise since 1958. In 1960 rather severe hypercalcaemia was found and hyperparathyroidism was diagnosed. At operation (February 1960) all the parathyroids were identified by biopsy and frozen section and the enlarged right and left upper parathyroids were removed (800 and 200 mg respectively). Until 1966 the serum calcium levels remained normal, but they have risen slightly (11·0–11·5 mg/100 ml) since then. In 1970 a silent stone in the left kidney was found on X-ray, and re-exploration of the neck followed (February 1971). The left lower parathyroid was enlarged (250 mg) and removed. The right lower gland could not be found in the scar tissue. Presumably this gland was also hyperfunctioning since her serum calcium levels are still slightly elevated.

Discussion

As stated earlier there are several possible explanations for the development of true recurrence of hyperparathyroidism after adequate operative treatment, and it is surprising to find only a few definite cases in the literature. That true recurrence is very rare is confirmed by the extremely low figure of 1 per cent in the present series. However, this shows that recurrence does not usually develop for some years. In the 4 patients reported here the periods of proved normocalcaemia were 7, 9, 8 and 6 years respectively, and second operations were performed 9–16 years after the first explorations. It seems likely that more cases of true recurrence may be expected in the future since hyperparathyroidism is now diagnosed earlier in the course of the disease than it was formerly, and patients are followed up more carefully. Clearly, meticulous exploration of all four parathyroids, with biopsy and frozen section of all the glands, is needed at the first operation. Adherence to these rules will probably reduce greatly the number of cases with persistent hypercalcaemia. Follow-up at regular intervals seems necessary for many years after operation. Only in this way can an accurate assessment of the incidence of truly recurrent hyperparathyroidism be obtained.

Recurrent pleural effusion in chronic relapsing pancreatitis

RUDRA RASARETNAM, A. B. V. PERERA AND M. KUMARASINGHE*

SUMMARY

A case of recurrent pleural effusion occurring in a patient with chronic relapsing pancreatitis is presented. Although it is one of the less common manifestations of the pleuropulmonary complications of pancreatitis, the presence of such a lesion is of diagnostic importance when the enzyme content of the effusion is elevated above the levels in the serum. In most of the reported cases resolution has occurred with conservative therapy, but failure to do so necessitated subtotal pancreatectomy, following which the patient made an uneventful recovery.

ALTHOUGH many accounts make no mention of the pleuropulmonary complications of pancreatitis, retrospective analyses have shown a high incidence of raised hemidiaphragm, basal atelectasis, pleural reaction and pleural effusion (Lipp and Aaron, 1950; Hammarsten et al., 1959; Kaye, 1968). Most of these reactions are non-specific, occurring in many acute upper abdominal lesions, mainly subphrenic abscesses (Ochsner and DeBakey 1938). Pleural effusions are reported to occur in between 3 and 38 per cent of cases of pancreatitis and are predominantly on the left, and although relatively uncommon, they can be of diagnostic significance when shown to contain a high level of pancreatic enzymes.

Case report

S. E. F., a 45-year-old man, was admitted to a medical unit of the Colombo General Hospital in March 1972 with a history of gradual onset of epigastric pain of 9 days' duration, which was becoming progressively worse. After a barium meal examination of the upper gastro-intestinal tract, which showed no abnormality, he was discharged on the ninth day, but was readmitted the same night with severe abdominal pain. At operation he had free fluid in the peritioneal cavity, the omentum was oedematous and there were numerous patches of fat necrosis. The pancreas was firm. A diagnosis of acute pancreatitis was made, and his postoperative recovery was uneventful.

The patient had been accustomed to taking half a bottle of arrack daily for the past 20 years, and he continued to do so after his discharge from hospital. Over the next 2 years he complained of attacks of abdominal pain, which lasted only 5 minutes and occurred shortly after the start of a meal. There was no radiation of pain and no vomiting.

In March 1974 he developed more severe abdominal pain, and 3 days before admission he also noticed increasingly severe pain in the right lower chest. He also complained of pain in the right shoulder and retrosternal pain which radiated up into the neck, but was not associated with sweating. He had had a mild dry unproductive cough for 3 weeks. On examination he appeared to be in considerable pain. The pulse rate was 80/minute and the blood pressure 110/80 mm Hg. No abnormality was found in the cardiovascular system. The trachea was central, and there was evidence of a right pleural effusion. The abdominal muscular tone was normal, but there was tenderness in the right hypochondrium. There was no ascites, and no abdominal viscera or other masses were palpable.

Investigations showed the following: haemoglobin 10·7 g/100 ml, PCV 87 per cent, WBC 10 900/mm^3, serum bilirubin 0·6 mg/100 ml, thymol turbidity 2 units, zinc sulphate turbidity 6 units. Over the next 2 days he continued to complain of abdominal and chest pain, and there was deterioration in his condition. The serum amylase was now 7300 Somogyi units/100 ml, and chest X-ray showed a diffuse opacity in the right chest. On 20 April 900 ml of straw-coloured fluid were aspirated from the right chest, and a further 1000 ml on 22 April. The pleural fluid contained amylase, 73 600 Somogyi/100 ml. Between 19 April and 10 May the effusion was aspirated on six occasions, but without remission of his symptoms. In view of the rapid reaccumulation of the right pleural effusion an intercostal tube was inserted on 12 May and left *in situ* for 4 days, but after its removal further reaccumulation of fluid necessitated its reinsertion. In view of the failure of conservative therapy and increasing pain it was thought that a more aggressive form of treatment was required. During the 5 weeks of preoperative treatment, the serum amylase varied between 1100 and 7300 Somogyi u./100 ml while the pleural fluid amylase was markedly elevated at between 2900 and 278 000 Somogyi u./100 ml (*Table I*). The urinary amylase and diastase levels were also elevated. The pleural aspirate remained straw-coloured until 6 May, when it became dark brown.

Table I: SERUM AND PLEURAL FLUID AMYLASE LEVELS

Date	Volume of pleural fluid aspirated (ml)	Serum amylase (Somogyi u./100 ml)	Pleural fluid amylase (Somogyi u./100 ml)
19 April	—	7300	—
20 April	900	—	—
22 April	1000	—	73 600
24 April	—	4000	—
25 April	—	5700	200 000
28 April	750	—	—
29 April	1000	—	287 000
8 May	—	3000	—
10 May	820	—	—
12 May	Intercostal tube inserted for 4 days		33 000
15 May	—	—	34 200
21 May	Intercostal tube reinserted		
23 May	—	1100	—
24 May	—	1400	2 900
25 May	Subtotal pancreatectomy		
10 July	—	265	—
15 Oct.	—	205	—

On 17 May the urinary amylase was 1200 Somogyi u./100 ml. On 24 May the urinary diastase was 128 Wohlemuth units.

At laparotomy on 25 May 1974 adhesions were found between the omentum, the transverse colon and the anterior abdominal wall. There was no free fluid. The duodenum and head of the pancreas were adherent to the posterior abdominal wall, but neither cysts nor fistulous tracts were present. The gallbladder and the extrahepatic biliary tree were normal. No communication was found between the peritoneal and pleural cavities. A subtotal pancreatectomy was performed, leaving 1 cm of pancreas adjacent to the duodenal curve. The pancreatic duct showed a stricture at the ampulla of Vater. This was dilated and the distal end of the transected pancreas and its duct were implanted into the posterior surface of the stomach. The postoperative course was complicated by the pleural fluid becoming frankly purulent and by the development of a pleurocutaneous fistula after removal of the intercostal tube. Subsequent recovery was uneventful. The serum amylase level gradually returned to normal, being 305 Somogyi units when the patient was discharged 12 days later.

---

* Colombo General Hospital, Sri Lanka.

On histological examination the pancreas showed marked infiltration with thick bands of fibrous tissue which passed between the lobules. The fibrous tissue was mature with few fibroblasts and was infiltrated by chronic inflammatory cells, mainly lymphocytes and plasma cells. Many of the pancreatic ductules were dilated. A few of the ducts contained an inflammatory exudate with polymorphonuclear leucocytes. Some of the blood vessels showed endarteritis obliterans, and one blood vessel contained an infected thrombus. The remaining pancreatic tissue, both endocrine and exocrine, appeared normal.

When reviewed in October 1974 the patient appeared well and had had no further attacks of abdominal pain. The serum amylase was 205 Somogyi/100 ml.

Discussion

Pleural effusion is now recognized as a complication of acute pancreatitis. It usually occurs on the left, but may be bilateral (Lipp and Aaron, 1950; Roseman et al., 1960; Kaye, 1968). Similar features have been described with chronic relapsing pancreatitis (Mitchell, 1964; Miridjanian et al., 1969). The diagnostic significance of a high level of amylase in the pleural fluid was first described by Werner (1942), and since then Kaye (1968) has collected 37 such cases from the literature. Hammarsten et al. (1959) investigated 12 patients with pleural effusion which was not associated with pancreatic disease and found that, although the pleural amylase level was mildly elevated, it was always below the level of the serum amylase. They thought that a pleural fluid amylase level of over 200 Somogyi units was suggestive of pancreatic disease. More recently, Bellman and Rajaratnam (1974) have described 2 patients with perforation of the oesophagus in whom the pleural fluid amylase was elevated and above that of the serum amylase. They suggested that the enzyme was derived from the swallowed saliva.

The mechanism of formation of pleural effusions in pancreatic disease has been the subject of much interest. As in other acute upper abdominal lesions, the effusion could occur as a sympathetic effusion consequent upon an irritation of the diaphragm, but in such cases the enzyme content would not be elevated above the serum levels. Transmission of peritoneal fluid through the normal apertures in the diaphragm would imply the formation of a mediastinal pancreatic pseudocyst which had subsequently ruptured into the pleural cavity, but this has rarely been described. Blood-borne transfer of pancreatic enzymes is also unlikely, since in such cases there would be an equal incidence of pleural effusions on the two sides, and the amylase levels would be the same as in the serum. The greater incidence of left-sided pleural effusions has been explained by the more intimate relationship of the left hemidiaphragm with the pancreas. The frequency with which pseudocysts have been associated with pleural effusions has suggested the possibility of transdiaphragmatic rupture, which would account for the high amylase content in the pleural fluid (Hunt, 1954; Goldman et al., 1962). Such cases are, however, rare, the majority of pancreatic pseudocysts having no communication across the diaphragm (Hammarsten et al., 1959).

The presence of numerous lymphatic pathways between the upper abdominal and thoracic cavities and the rapid transfer of enzymes and particulate matter from the peritoneal cavity into the mediastinal lymph nodes and the thoracic duct in experimental animals suggest that pancreatic enzymes may reach the pleural fluid via the lymphatics in man (Cunningham, 1922; Perry, 1947). Pancreatic enzymes, on account of their large molecular weight, are unlikely to be transferred directly from the pancreas into the blood capillaries, and they may be carried in the lymph to the thoracic duct (Dumont et al., 1960).

Obstruction to the outflow of the pancreatic duct, as in the case reported here, increases the movement of pancreatic enzymes into the interstitial fluid, and thence into the lymphatics and the thoracic duct (Bartos et al., 1966). The theory of lymphatic transfer of pancreatic enzymes seems the most attractive of the various mechanisms that have been postulated to explain the accumulation of pancreatic enzymes in pleural effusions in pancreatitis. It would seem to be applicable to our patient, in whom no abnormal pathways across the diaphragm were demonstrated and in whom neither intraperitoneal free fluid nor pseudocyst was present. Obstruction at, or close to, the ampulla of Vater would have caused a maximal rise in intraductal pressure close to the ampulla, hence accounting for the formation of a right-sided pleural effusion.

Most of the reported cases with pleural effusions have been successfully managed on conservative lines, although thoracotomy and decortication have been necessary in some (Mitchell, 1964). In the present patient persistent abdominal symptoms and chest pain, together with the rapid reaccumulation of an enzyme-rich pleural effusion and deterioration in his general condition, prompted a more aggressive approach. Subtotal pancreatectomy was followed by complete relief of symptoms. It is possible that dilatation of the pancreatic duct would have sufficed and such a procedure may be worthy of trial.

Xanthogranulomatous pyelonephritis: a report of 2 cases

O. S. MORGAN, G. D. NICHOLSON, P. S. JOHNSON AND D. W. ATKINSON*

SUMMARY

Two cases of xanthogranulomatous pyelonephritis are reported in Negroes. The clinical findings are similar to those in previously reported cases. In 1 case nephrolithotomy was followed by the development of a perinephric abscess 8 months later. Late diagnosis has limited experience with more conservative management, which should be reserved for demonstrably focal disease.

XANTHOGRANULOMATOUS pyelonephritis is an infrequently occurring variant of pyelonephritis rarely reported in Negroes. In a review of 38 cases in whom ethnic origin was noted only 10 per cent occurred in Negroes (Anhalt et al., 1971). We report 2 cases of this condition in patients of African descent, in one of whom management by removal of the associated renal calculus was unsuccessful.

Case reports

Case 1: A 67-year-old housewife was admitted to the University Hospital, Kingston, after an 8-week period of increasing ill-health. During the previous 4 months she had experienced intermittent episodes of pain in the left flank and iliac fossa, accompanied by increased frequency of micturition. In the 4 weeks antedating admission she had complained of lassitude, chills, rigors and night sweats. She had lost over 13 kg in weight since the onset of her illness.

On examination a large non-tender irregular mass was palpable in the right hypochondrium. The urine contained many pus cells and a few red blood cells, but was sterile on culture. The haemoglobin was 8·6 g/100 ml, the white cell count 8100/mm^3 with a normal differential, and the ESR 100 mm in 1 hour. Blood cultures were sterile. The blood urea was 28 mg/100 ml and the plasma creatinine 1·0 mg/100 ml. An abdominal film revealed a large soft tissue mass in the left upper quadrant with a dense opacity within its borders. Intravenous pyelography showed only faint excretion of the dye on the left side. The left renal outline was enlarged and calicectasis was observed in the upper pole. No caliceal pattern was distinguishable in the lower pole which contained a large calculus. The right kidney functioned normally. At cystoscopy there was milky urine coming from the left ureter, whose orifice was grossly oedematous. A left retrograde pyelogram confirmed the presence of calicectasis. Pus obtained at this examination was sterile. At nephrectomy a large hydronephrotic kidney was found. The perinephric tissues were grossly oedematous and the kidney was adherent to the spleen and descending colon.

The kidney was 17 cm long and weighed 300 g. The calices were enormously distended by thin pus and there was fibrotic thickening of their walls. There was severe loss of renal parenchymal tissue. A large calculus 3 cm in diameter lay within a lower pole calix. Multiple yellow nodules measuring up to 2 cm in diameter were scattered throughout the solid areas of tissue (*Fig*. 1).

The histological appearances were of acute on chronic pyelonephritis with widespread xanthogranulomatous change. The renal parenchyma was almost entirely destroyed apart from a few remnant tubules containing hyaline casts. There was extensive fibrosis and scattered abscess formation. The dense infiltration of inflammatory cells included neutrophils, plasma cells and lymphocytes with follicle formation. In addition, abundant foamy histiocytes were present, often forming large aggregates. Oil-Red O stains confirmed these cells to be rich in cytoplasmic lipid. Very few giant cells were found (*Fig*. 2).

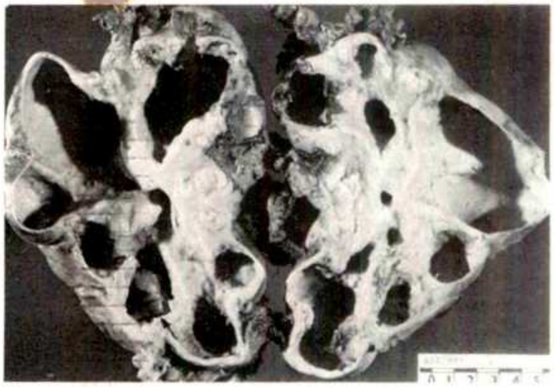

Fig. 1. *Case* 1. Photograph of the bisected kidney showing the grossly dilated caliceal system. The renal parenchyma is almost indistinguishable, being replaced by yellow nodules. The arrow points to the calculus in a lower pole calix.

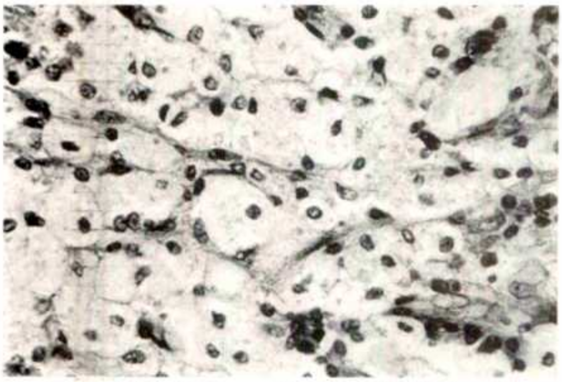

Fig. 2. *Case* 1. Photomicrograph showing lipid-laden histiocytes. (× 210.)

Case 2: A 51-year-old housewife was transferred to the University Hospital, Kingston, for investigation of a non-functioning left kidney. A large calculus had been removed from the left renal pelvis 8 months previously. Two months prior to admission she had been treated for a urinary tract infection and 2 weeks later had developed a left perinephric abscess which, although widely incised and drained, had continued to discharge.

On examination the patient seemed surprisingly well. She was afrebile. Large quantities of foul-smelling pus could be expressed from the left loin wound and yielded a mixed growth of *Staphylococcus pyogenes*, *Proteus* sp. and *Pseudomonas pyocyanea*. Intravenous pyelography showed a non-functioning left kidney; the right kidney was normal. Retrograde pyelography was unsuccessful. At operation a large pyonephrosis was found. The kidney was removed with difficulty from the surrounding tissues to which it was extremely adherent.

---

* Departments of Medicine, Surgery and Pathology, University of the West Indies, Mona, Kingston 7, Jamaica, West Indies.

The kidney was 12 cm long and weighed 150 g. The calices, which were dilated, had thickened walls and haemorrhagic mucosa. The renal parenchyma was greatly reduced, pale in colour and contained multiple yellow nodules of variable size, averaging 1 cm in diameter, and frequently bordering the calices. No calculi were found. There was severe acute on chronic pyelonephritis with extensive destruction of renal parenchyma and abscess formation. The inflammatory infiltrate contained numerous neutrophils, plasma cells and lymphocytes with follicle formation. Many foamy histiocytes forming large aggregates were present. These cells were rich in cytoplasmic lipid. An occasional multinucleate giant cell was also present.

Discussion

These cases are similar to those reported previously, in which the prominent features include an enlarged non-functioning kidney associated with renal calculi, obstruction and chronic infection. The interest in this condition lies in the importance of its differentiation from carcinoma and tuberculosis of the kidney on clinical, radiological and pathological grounds, permitting a planned approach to therapy.

Malek et al. (1972) have suggested the classification of xanthogranulomatous pyelonephritis into three stages. Our cases fall into stage III of this classification, with nephric, perinephric and paranephric involvement in which removal of the diseased kidney is the treatment of choice. The disease does not tend to recur after nephrectomy even following incomplete excision (Elliott et al., 1968; Malek et al., 1972), and this strongly suggests the pre-eminence of local rather than metabolic factors in its causation.

Anhalt et al. (1971) treated one of their patients with rare bilateral disease by nephrolithotomy with a favourable outcome. Our second case was treated by nephrolithotomy at a time when the diagnosis was unsuspected. The subsequent development of a perinephric abscess is indicative of persistent infection in that kidney. Diffuse involvement of the affected kidney has commonly preceded diagnosis and this has limited attempts at conservative management. Nephrolithotomy, alone or combined with partial excision, should be confined to the focal form of the disease in which absence of function is confined to the abnormal portion of the kidney (Mitchell et al., 1959). Non-function of the whole kidney, particularly where the associated calculus lies in a polar calix, should alert one to the possibility of diffuse disease. Until earlier diagnosis becomes possible, attempts at local excision will remain exceptional and total nephrectomy the established procedure for diffuse disease.

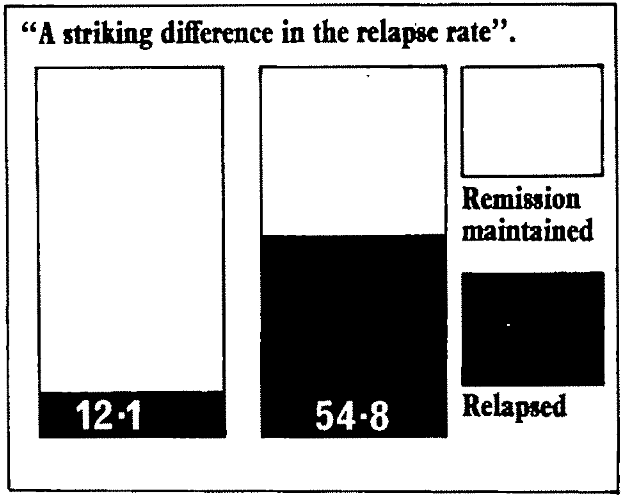
"It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects".[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford, are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be totally ineffective in reducing the number of recurrences of ulcerative colitis.

"Fortunately, Sulphasalazine tablets, 0.5 grams, 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely, since we do not know when, if ever, it can be safely stopped".[4]



"A striking difference in the relapse rate".

"The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine".[1] (Salazopyrin).

Salazopyrin (sulphasalazine) is available as the plain 0.5 g. tablet, 0.5 g. EN-tab and as an 0.5 g. suppository. Literature and detailed information on Salazopyrin are available on request.

An incision for *en bloc* nephrectomy

G. F. CASSIE*

SUMMARY

A surgical approach is described for en bloc removal of a large renal mass, enabling easy removal of such a mass with early palpation and ligation of the renal pedicle and with the minimum of assistance. The principle underlying the approach is that of detaching the costal margin and the free ribs from the abdominal musculature. In the experience of the author the wound always heals by first intention. No complications have been encountered and the patients have been discharged from hospital within 10 days of operation.

NEPHRECTOMY for a considerably enlarged kidney, in particular by malignant disease, commonly presents problems to the surgeon in his surgical approach. The standard loin incision with bridge or table break is unsuitable if the mass is large or the patient obese, as careful dissection of the pedicle becomes difficult, if not hazardous. The alternative thoraco-abdominal approach, which gives good exposure, is time-consuming and an additional burden to the patient, with increased time of anaesthesia and the risk of pulmonary complications.

During the past 8 years the author has used his approach on 8 occasions, 7 being for large hypernephroma masses and 1 for a huge myxoliposarcoma of the perinephric fat. On each occasion the wound has healed by first intention, no complications have been encountered and all the patients have left hospital within 10 days of operation. The principle underlying

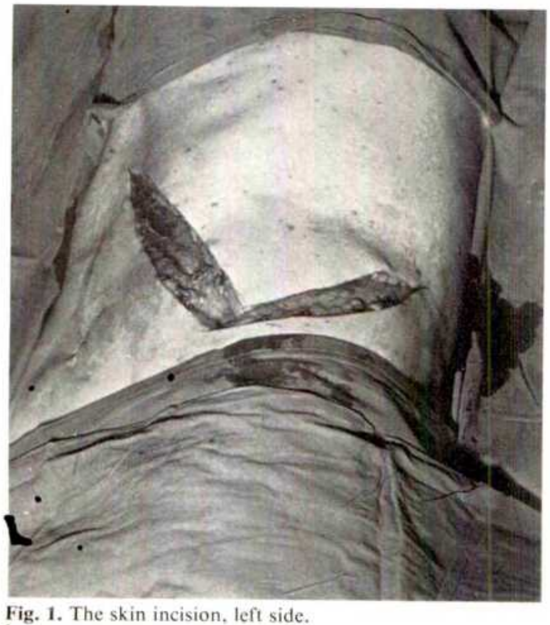

Fig. 1. The skin incision, left side.

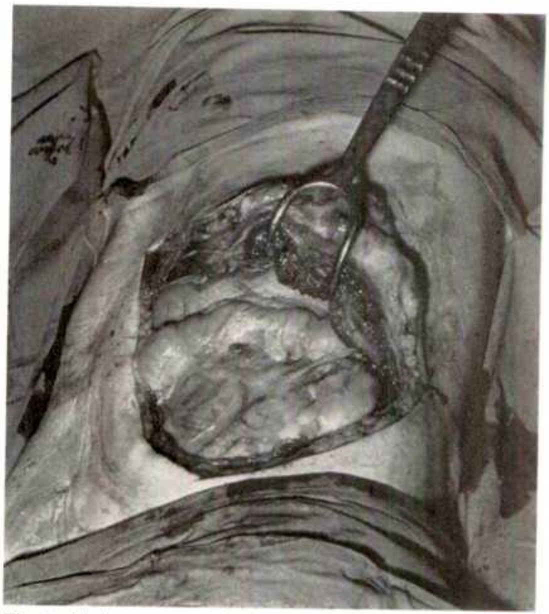

Fig. 2. Abdomen entered. The costal margin is elevated by a single retractor, displaying the splenic flexure of the colon overlying the renal mass.

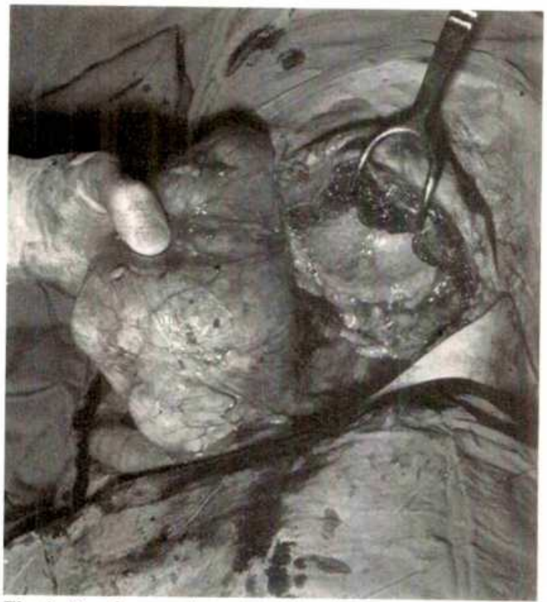

Fig. 3. Renal mass elevated *en bloc* from the posterior abdominal wall and rotated to the contralateral side to permit dissection and ligation of its pedicle.

---

* Queen Elizabeth II Hospital, Welwyn Garden City.

the approach requires the detachment of the costal margin and free ribs from the abdominal musculature, enabling an excellent exposure of the subdiaphragmatic area by elevation of the rib cage with one retractor.

The incision

The patients lies supine but tilted 45° to the opposite side by sandbags placed behind the scapula and buttock. The incision consists of a Kocher subcostal incision joined to a short incision into the loin just below the tip of the 11th rib (*Fig*. 1). The surgeon stands on the contralateral side. The muscles are cut by diathermy and the peritoneum entered (*Fig*. 2). A thorough examination of the abdominal contents can now be carried out. The flexure of the colon is stripped medially, displaying the renal mass within its perinephric capsule. This can now be elevated from the posterior abdominal wall (*Fig*. 3), enabling identification, inspection, palpation and ligation of the vascular pedicle. The adrenal is usually taken in the tissue block, its vessels being readily seen. The anterior and lateral peritoneum can be reconstituted during catgut suture of the abdominal wall with incorporation at the posterior end of a drain, which can be removed at 48 hours, the patient then being ambulant. Sutures are removed on the seventh day (*Fig*. 4). The huge solid tumour—a myxoliposarcoma—removed from the patient illustrated is shown in *Fig*. 5.

This approach is recommended to surgeons faced with removal of a large renal mass, as it permits a safe *en bloc* excision with the minimum of assistance. No mention of this incision is to be found in the standard texts on surgery or urology.

Undetected aorto-iliac insufficiency: a reason for early failure of saphenous vein bypass grafts for obstruction of the superficial femoral artery

D. CHARLESWORTH, P. L. HARRIS, F. D. CAVE AND LINDA TAYLOR*

SUMMARY

A series of 29 femoropopliteal bypass operations is described. The patients were selected carefully to exclude those with clinical and aortographic evidence of aorto-iliac disease. A pulsatility index was calculated from the velocity waveforms recorded over the common femoral and popliteal arteries. The pulsatility index is the ratio of the amplitude of the waveform to its mean height over one cardiac cycle. There was a highly significant difference in the result of the operation between patients with a pulsatility index of 4 or more in the common femoral artery and patients with a pulsatility index of less than 4. We concluded that calculation of this pulsatility index provides useful additional evidence when selecting patients suitable for a femoropopliteal bypass.

VARIOUS methods of reconstructing the superficial femoral artery have been tried in patients with chronic ischaemia of the lower limb and symptoms of intermittent claudication or pre-gangrene. There is little doubt that at present a reversed saphenous vein bypass graft is the most effective method of reconstruction when the superficial femoral artery is occluded (Szilagyi et al., 1964; Gutelius et al., 1965; DeWeese et al., 1966; Baddeley et al., 1970; DeWeese and Rob, 1971; Imperato et al., 1973; Watt et al., 1974), but even in the most experienced hands the operation is not an unqualified success. Most surgeons report that approximately one-third are occluded within 2 years of operation. When the operation is done for pre-gangrene or gangrene the failure rate is between 50 and 70 per cent (Tibbs, 1960; Taylor, 1962). The yearly failure rate in a group of our patients who had a femoropopliteal vein bypass and were followed up for 4 years is shown in *Fig*. 1. The majority of grafts occlude shortly after operation and it is obvious that it is not progression of disease which is responsible. Provided that the vein exceeds 4 mm in diameter and the operation is performed skilfully, it is probable that success or failure depends upon an adequate flow of blood into the graft from the common femoral artery and an adequate outflow into the tibial vessels—'run-off'. Measurement of run-off in the lower leg before operation has been attempted by several methods but the results have had little influence on the selection of patients for operation (Agrifoglio et al., 1961; Lassen et al., 1964; Dahn, 1965; Strandness and Bell, 1965; Mundth et al., 1969; Yao et al., 1970). In patients with a significant pressure drop along the iliac arteries a reconstruction of the iliac artery performed in conjunction with the femoropopliteal bypass graft increased the chances of the graft remaining patent. This information was obtained by direct recording at the time of operation (Moore and Hall, 1971). Similar information can be obtained before operation from waveform analysis of ultrasound signals and this information can be obtained non-invasively. We have studied the velocity waveforms in a series of 29 consecutive patients with occlusion of the superficial femoral artery, all of whom had a reconstruction using a reversed saphenous vein bypass graft.

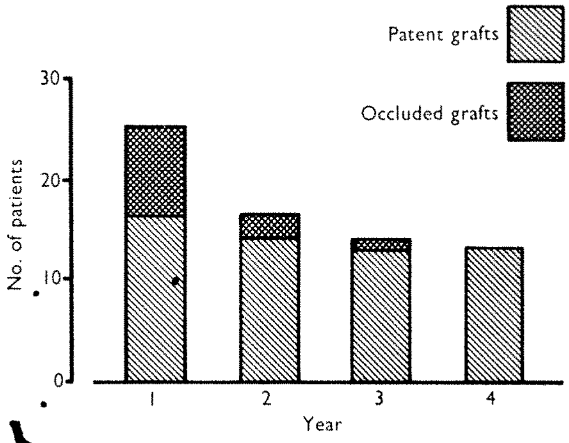

Fig. 1. Histogram showing a group of 25 patients who had a femoropopliteal bypass and were followed up for 4 years. The numbers of grafts which occluded in each year is shown as cross hatched.

Patients and methods

The investigation was carried out on a carefully selected group of patients with arteriosclerosis who had either symptoms of intermittent claudication of sufficient severity and duration to interfere seriously with their activities or pre-gangrene. Patients who had clinical evidence of aorto-iliac disease were excluded. The remaining patients were admitted to hospital for an aortogram, and X-rays were taken of the entire arterial tree from the aorta to the ankles. Patients with radiographic evidence of aorto-iliac stenosis or occlusion were treated by reconstruction of that segment and were not included in this series. Only patients whose arteriograms showed a complete occlusion of the superficial femoral artery and arteriographic grade 0 or 1 disease in the aorto-iliac segment were selected for a femoropopliteal bypass

Graft after 6 months	15	3
Graft occluded within 6 months	2	9

(Harris et al., 1973, 1974). No attempt was made to select patients for operation on the basis of run-off. If the X-ray showed that the popliteal artery was patent the operation was considered to be technically possible.

Twenty-nine patients were studied, 23 male and 6 female, with an average age of 58·5 years (range 44–79 years). Twenty-one of the operations were for intermittent claudication and 8 were for pre-gangrene. Velocity waveforms were recorded from the common femoral, popliteal and tibial arteries of each patient before operation and again 6 months afterwards. The velocity waveforms were displayed as a sonagram and characterized by a single figure, the pulsatility index (*Fig.* 2) (Gosling et al., 1972; Harris et al., 1974). A subjective assessment of the result of each operation was made from the patient's symptoms. The results of preoperative measurements of pulsatility were compared with the subsequent results of the operation. All the operations were carried out by the same surgeon, and exactly the same technique was used in every patient.

Results

There were 21 patients with symptoms of intermittent claudication. Fifteen of these patients had a pulsatility index of 4 or more in the common femoral artery on the affected side, and 6 had a pulsatility index of less than 4. Thirteen (87 per cent) of the 15 patients who had a femoral pulsatility index of 4 or more had patent vein bypass grafts after an interval of 1 year. Eight patients had pre-gangrene and only 2 of these had a pulsatility index greater than 4 in the common femoral artery on the affected side. Both of these patients had a patent graft at follow-up (*Table I*). A total of 17 patients had a pulsatility index greater than 3·9 in the common femoral artery, and 15 (88 per cent) of these had patent vein bypass grafts at follow-up. In 12 patients the pulsatility index in the common femoral artery on the affected side was less than 4, and only 3 (25 per cent) had a patent graft at follow-up (*Table II*, *Fig.* 3).

Preoperatively the pulsatility index in the ipsilateral popliteal arteries was 1·9 ± 1·0 (normal range 9·4 ± 3·5) and in the posterior tibial arteries it was 1·6 ± 0·94 (normal range 8·3 ± 3·0). When the operation was successful the pulsatility index in the popliteal artery and posterior tibial artery increased invariably (*Fig.* 4). The mean pulsatility index in the popliteal artery rose from 1·9 to 6·8 (Student's t-test, $P < 0{\cdot}001$) after operation, and in the tibial artery it rose from 1·8 to 4·9 (Student's t-test, $P < 0{\cdot}001$).

Discussion

The patients who were included in this study were selected for a vein bypass operation without reference to the results of the pulsatility measurements. Patients who had angiographic evidence of disease in the aorto-iliac segment were excluded from the study and had a reconstruction of this segment in preference to a femoropopliteal vein bypass graft. No attempt was made to select patients on the basis of assessment of run-off; if the popliteal artery was visible on the angiogram a graft was considered to be technically possible. We divided the patients into two groups on the basis of the common femoral pulsatility index. The lower limit of pulsatility in the common femoral artery is 4 in normal volunteers and we regard values of less than 4 to be indicative of disease in the aorto-iliac segment (Harris et al., 1974). Patients with angiographic evidence of aorto-iliac stenosis were eliminated by the preoperative selection process, and consequently the 12 patients who had a pulsatility index of less than 4 in the common femoral artery had disease in the iliac arteries, the severity of which was not apparent on the angiograms. In general, there is a good correlation between angiographic appearances and the pulsatility index, but velocity waveform analysis can detect disease which is not apparent on single-plane angiograms (Harris et al., 1974).

There was a highly significant difference between the results in the patients with a normal common femoral pulsatility and those with an abnormal one ($P < 0{\cdot}003$, χ^2 test). A high percentage (88 per cent) of the patients who had claudication only and a normal pulsatility index in the common femoral artery had a patent graft after an interval of 12 months from the operation. The vein bypass graft occluded early in only 2 patients out of the 17 who had normal pulsatility indices. Both of these had angiographic evidence of poor run-off; in one none of the tibial vessels was patent, and in the other only one tibial artery was patent and the others were absent. We were unable to demonstrate any correlation between the pulsatility index measured in the popliteal artery or the posterior tibial arteries and the result of a vein bypass operation. The extent to which an arterial velocity wave is damped between the knee and the ankle can be assessed from the ratio of the pulsatility index in the popliteal artery to the pulsatility index in the posterior tibial arteries (Gosling et al., 1972). This value did not correlate well with the result of the operation and it did not prove to be a useful measure of run-off. The value of the pulsatility index at these two sites did give a good indication of whether a graft was patent and it provided a useful objective measurement when assessing patients at follow-up. Our results are in accord with previous clinical experience, in that the flow of blood into a femoropopliteal bypass is more important than run-off (Linton and Darling, 1962; Mavor, 1973; Horton, 1974).

The implication of these results is that patients who are selected for a femoropopliteal vein bypass operation on the basis of their clinical symptoms and angiograms should also have a pulsatility index of more than 3·9 in the common femoral artery in order to stand the best chance of success. When the pulsatility index on the side of the proposed operation is less than 4 it is now our practice to explore the aorto-iliac segment. We anticipate that this will yield more information about the influence of this segment of the arterial tree on the outcome of a femoropopliteal bypass graft.

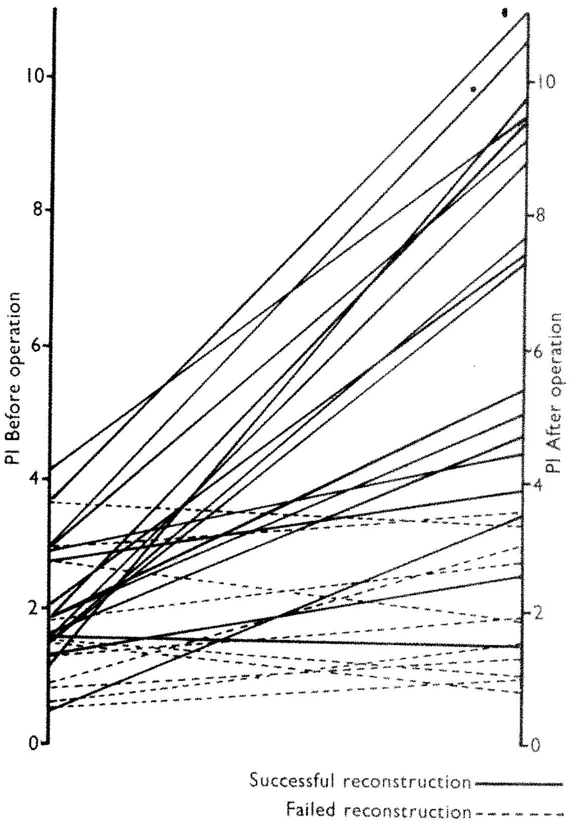

Fig. 4. Comparison between the pulsatility index in the popliteal artery before and after operation.

Ossification in extradural fat in Paget's disease of the spine

PATRICK R. R. CLARKE AND H. I. WILLIAMS*

SUMMARY

A case of cauda equina compression by ossification in extradural fat at a level above the site of Paget's disease in a vertebra is described. Good recovery followed laminectomy and exposure of the dura mater.

DYSFUNCTION of the spinal cord or the cauda equina in cases of Paget's disease of vertebrae is well recognized. The causes of this (Sadar et al., 1972) are usually thought to be compression by bone, fracture dislocation or vascular occlusion. In this paper we describe a case in which the cauda equina was compressed by spicules of bone in extradural fat at a level slightly above the site of the vertebra which was affected by Paget's disease.

Case report

A 52-year-old quantity surveyor had complained of low back pain, particularly after physical exertion, for 12 years. He was admitted to the Neurosurgical Unit of Middlesbrough General Hospital on 15 January 1974 because of progressive weakness of the left leg of 3 months' duration. His walking was affected to the extent that he could hardly hobble around his house. Examination showed 3 cm of wasting of the left thigh, weakness of the flexors of the left knee joint, a depressed left knee jerk and absence of the left ankle jerk. There was no sensory loss. Radiographic examination (*Fig.* 1) revealed Paget's disease of the 3rd lumbar vertebra. Urinary hydroxyproline excretion was 12 mg in 24 hours. The level of alkaline phosphatase in the serum was 19·6 KA u./100 ml. Myelography was performed by the cisternal route, as an attempt at lumbar puncture had been unsuccessful. This investigation showed (*Fig.* 2) a total block at the level of the 2nd lumbar vertebra. On 30 January 1974 laminectomy of the 2nd and 3rd lumbar vertebrae was performed. The bone of the 3rd lumbar vertebra was soft and very vascular. At the 2nd lumbar vertebral level the extradural fat was abnormally firm and was indenting the dura mater. The fat at the 3rd lumbar level appeared normal to the naked eye. Exposure of the theca was achieved by removal of the extradural fat.

Histological examination of the bone of the 3rd lumbar vertebra (*Fig.* 3) showed the characteristic changes of Paget's disease. The extradural fat from the 2nd lumbar level (*Fig.* 4) contained fibrous tissue and spicules of newly formed bone.

Progress after operation was smooth. The left leg rapidly became stronger, and 6 weeks after surgery the patient was able to walk a mile at a reasonable speed.

Discussion

The interest in this case before operation lay in the fact that the obstruction to downward flow of Myodil was at the level of the 2nd lumbar vertebra, whereas the Paget's disease appeared radiologically to be confined to the 3rd lumbar vertebra. Sarcomatous change and extension into the extradural space were considered as a possible explanation of this. The operative and histological findings, however, made it clear that the cause of the compression of the theca was ossification in the extradural fat. The literature on neurological dysfunction in Paget's disease of the vertebral column has recently been reviewed by Sadar et al. (1972), who added 4 cases of their own to the 86 reported by previous authors. In the same year Cartlidge et al. (1972) described 3 further cases. As far as we are aware, ossification in extradural fat in this condition has not previously been reported. Subperiosteal bone spiculation is, on the other hand, well recognized (Direzke and Milnes, 1970). According to Klenerman (1966) the dura mater is densely adherent to the adjacent bone in Paget's disease of the spine, but this was not our experience in the present case.

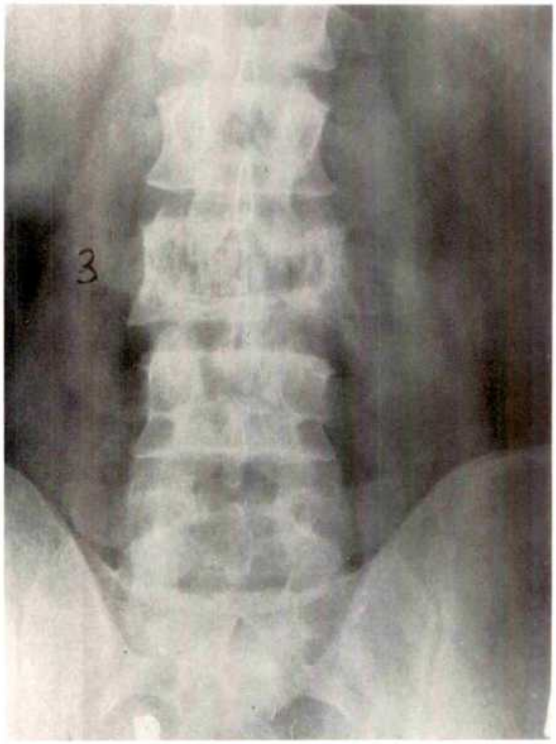

Fig. 1. Radiograph showing Paget's disease of the 3rd lumbar vertebra.

Although severe neurological deficit associated with Paget's disease of the spine makes surgery necessary, the place in the future of calcitonin M therapy both as a primary treatment and as a prophylactic against recurrence will need to be considered. Falls in serum alkaline phosphatase levels during calcitonin therapy have been held (Woodhouse et al., 1971) to be due to a reduction in the number or activity of osteoblasts.

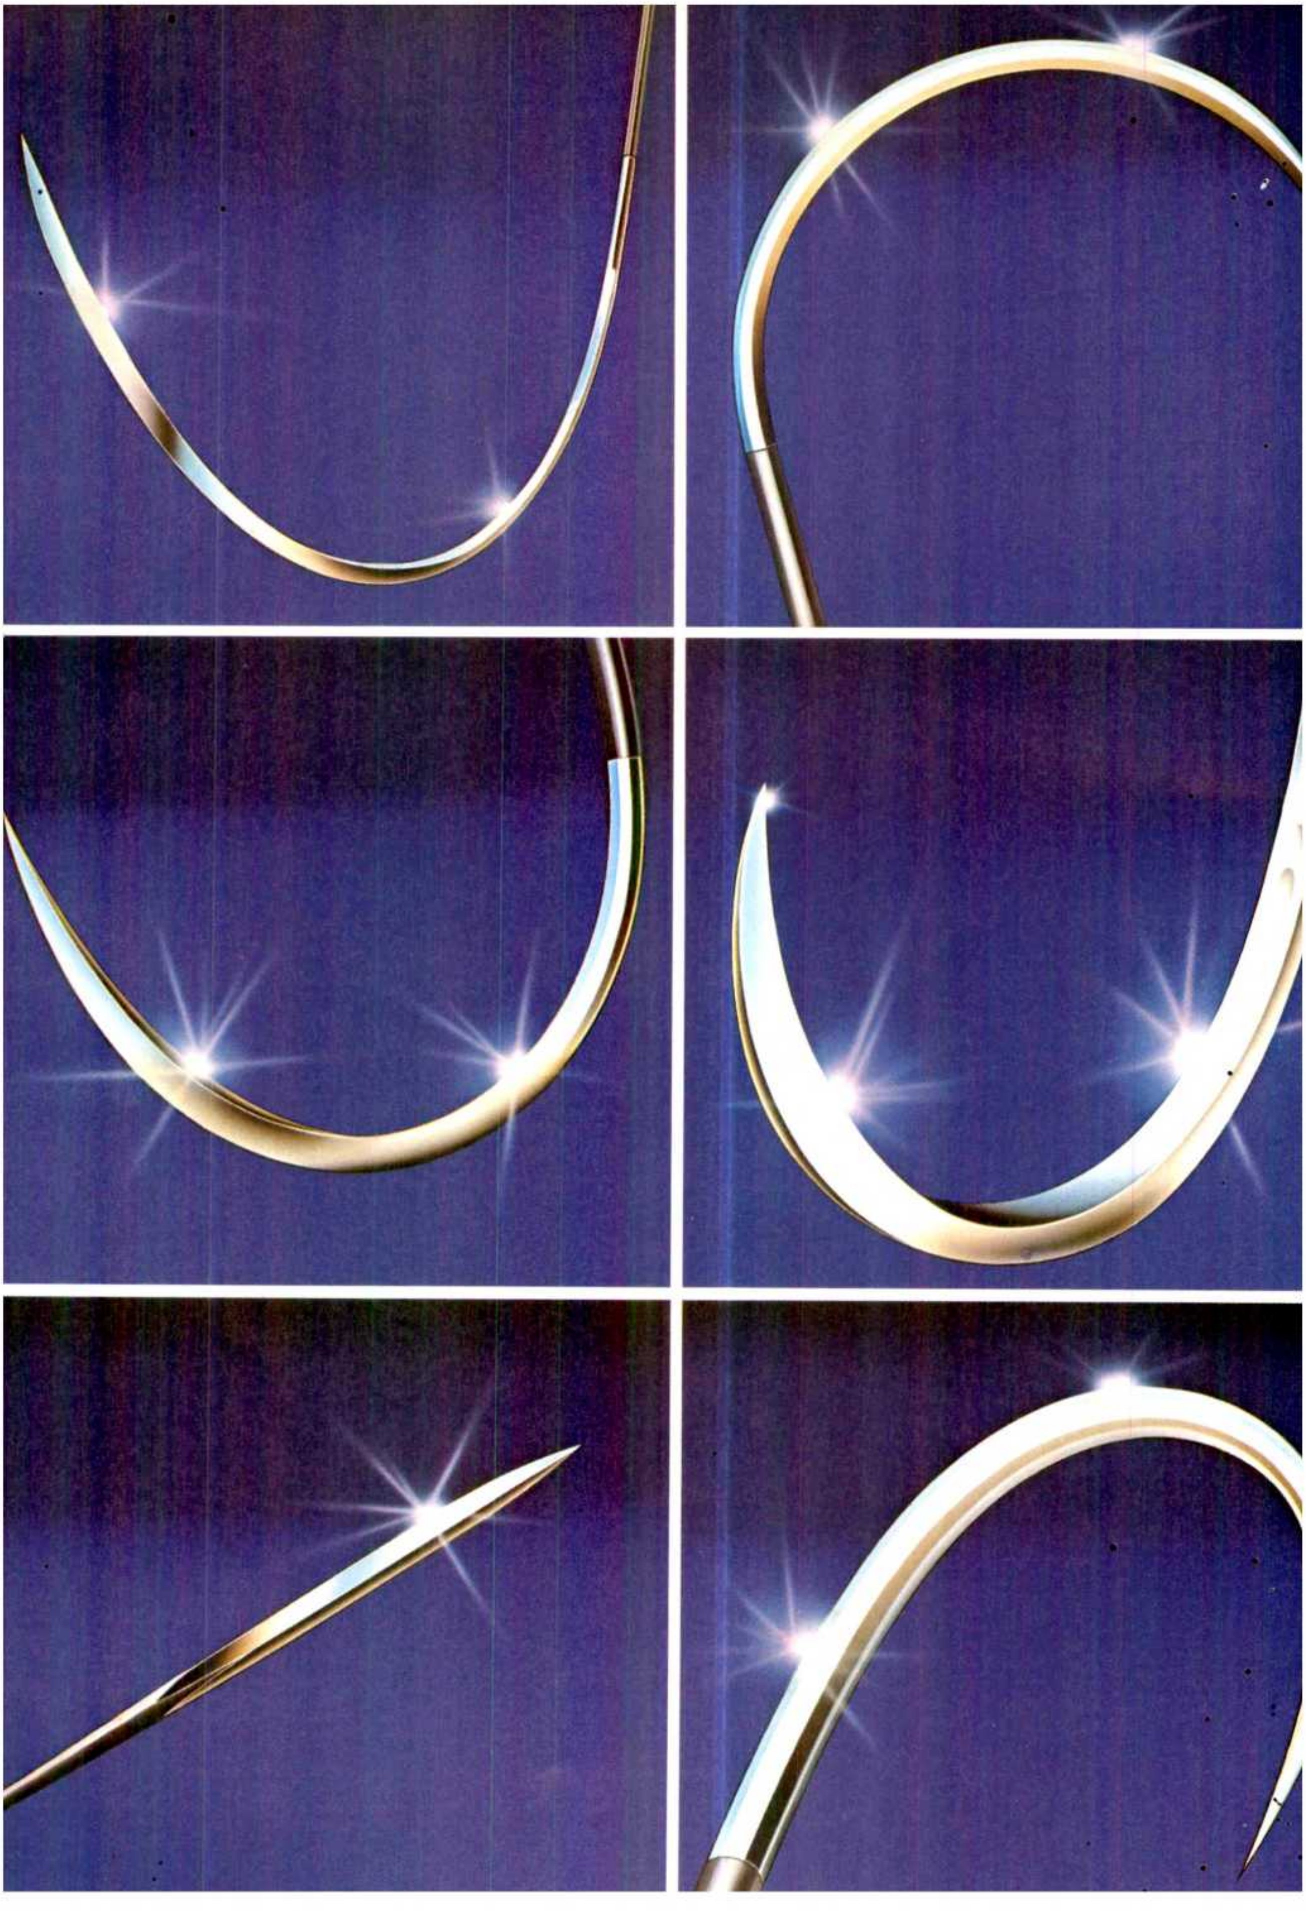
ETHICON
TRADEMARK
Eyeless needled sutures



WE MAKE SOME VERY IMPORTANT POINTS

ETHICON* Eyeless Needled Sutures offer three outstanding advantages over traditional eyed needles.

Point 1 A new sharp needle every time.

Point 2 Reduced trauma–with ETHICON eyeless needles there is no large eye and only one strand of material to pass through tissue.

Point 3 Consistent high quality–by precisely controlled manufacture of a complete sterile suture in a single package.

The choice is yours

Most surgeons agree that there is no universal suture. Most probably there never will be. Each patient, each procedure, and each layer of tissue differs from the next. This is why we at ETHICON manufacture such a comprehensive range of eyeless needled sutures.

You can choose from our wide selection of materials, absorbable and non-absorbable, securely attached to a stainless steel needle of your choice. The consistent high quality of ETHICON eyeless needled sutures provides predictable performance. This enables you to concentrate on the most critical aspect of your surgery–the well-being of the patient.

TRADEMARK
Eyeless needled sutures

Widest range. Finest quality

ETHICON Ltd., Bankhead Avenue, Edinburgh EH11 4HE, Scotland

PROLENE* Monofilament polypropylene
for security you can count on

When the reliability of a non-absorbable is required in a contaminated or potentially contaminated field many surgeons are now choosing PROLENE suture. Made from polypropylene, a material of relative biological inertness, monofilament PROLENE suture is not degraded by tissue enzymes and is virtually unaffected by the presence of infection.

Security for extended approximation

Where wound healing may be delayed PROLENE suture can be relied on to retain its tensile strength.

Secure knot-holding

PROLENE suture is able to deform and flatten on knotting to give knot security superior to any other monofilament.

Security through reduced risk of suture extrusion and sinus formation

The specially smooth monofilament structure of PROLENE suture and its ability to tolerate infection extremely well can lessen the risk present with a braided suture in a contaminated wound.

Indications: PROLENE Polypropylene suture may be used wherever a non-absorbable surgical suture is recommended.

Precautions: Unused PROLENE sutures may not be autoclaved more than three times by the standard autoclaving method without loss of strength. Care should be taken to avoid damaging the surface of the material with surgical instruments.

Nodular fasciitis: an unusual cause of extradural spinal cord compression

R. P. SENGUPTA, S. C. SO AND R. H. PERRY*

SUMMARY

A case of nodular fasciitis causing extradural spinal cord compression with a successful outcome following removal is reported. Such a tumour within the spinal cord has never been reported. The pathogenesis of a nodular fasciitis in this situation and its differential diagnosis is discussed.

NODULAR fasciitis is a well-recognized tumour occurring in the subcutaneous tissues over the trunk and limbs but has never been observed in the spinal canal. The following is a case report of such a tumour arising in the extradural space and causing spinal cord compression.

Case report

A 64-year-old retired schoolteacher was admitted to the Regional Neurological Centre in January 1974 with a 1-month history of lower thoracic back pain. It was constant and radiated to the right hypochondrium. Three weeks before admission he had noticed that he was unsteady on walking and that his legs had become weak. Shortly afterwards he developed hesitancy and urgency of micturition. Two days before admission he was unable to walk. For the past 8 years he had had hypertension and 2 years previously had had a cerebrovascular accident causing a left hemiparesis.

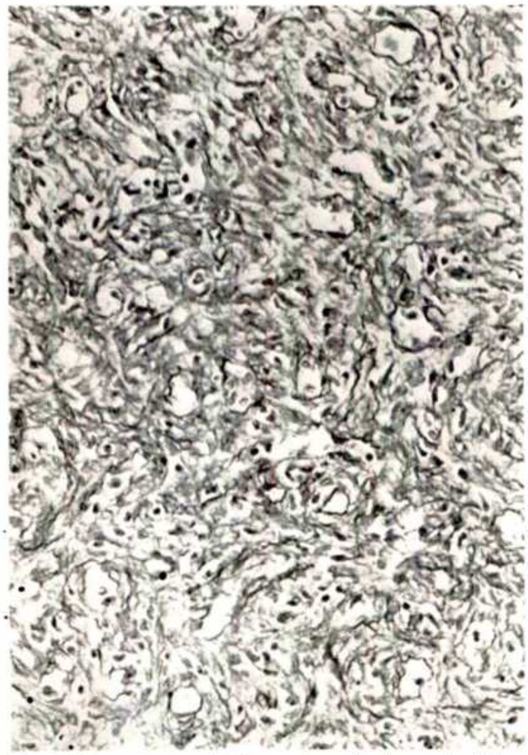

Fig. 1. Photomicrograph illustrating a haphazard cellular arrangement with reticulin fibres outlining cells and demarcating vascular spaces. Reticulin. (× 120.)

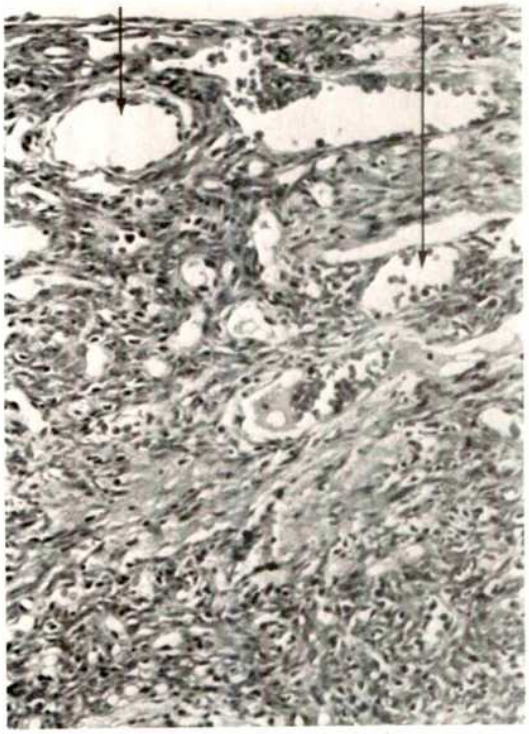

Fig. 2. Photomicrograph illustrating marked vascularity of the edge of the lesion. Arrows point to vascular spaces. HE. (× 160.)

On examination the patient had a localized tenderness over the spine of D9. Marked weakness was present in both lower limbs involving all muscle groups. There was no wasting, the tone was increased with brisk reflexes and the plantar responses were extensor. Pain and temperature sensation below the level of D9 were impaired. Both position and vibration sensations were absent below the hip joint and Romberg's sign was positive. He was hypertensive (220/130 mm Hg) with retinal vascular changes and left ventricular voltage changes on the ECG. Plain X-rays of the spine were normal. Myelography showed a complete block at D9 with features suggesting an extradural tumour. The cerebrospinal fluid protein was 76 mg per cent.

At operation the laminae from D8 to D11 were removed. A firm lobulated tumour was found in the extradural space pushing the cord anteriorly. The tumour was not attached to the dura or any nerve root. It was only loosely attached to

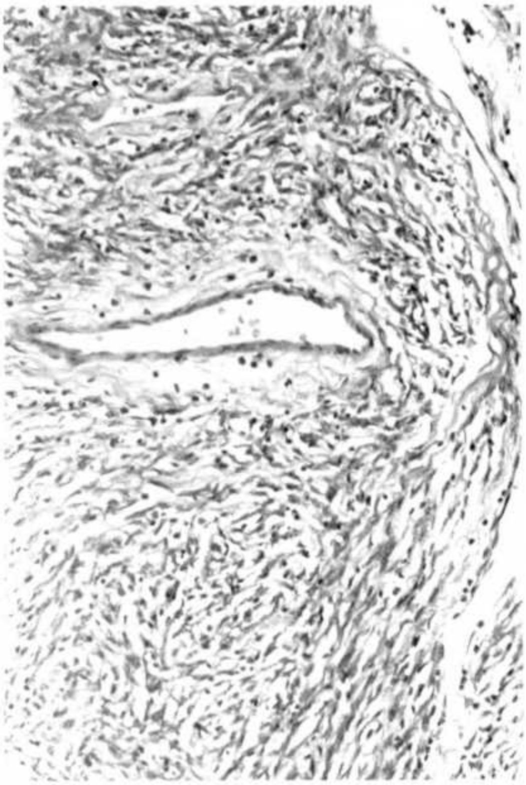

Fig. 3. Photomicrograph showing vascular clefts and intercellular spaces, many of which contain red blood cells. HE. (× 160.)

fibrofatty tissue and required little dissection for complete removal.

The patient made an uneventful recovery from the operation. Over a period of 4 weeks the power in the lower limbs returned to almost normal. The sensory deficit also recovered to a large extent and at the time of his discharge 4 weeks later he was able to walk unaided.

Histological examination revealed a circumscribed cellular nodule measuring 3·8 × 2·5 × 1·5 cm attached at one point to vascular fibrous fatty tissue. An incomplete fibrous capsule partially defined the edge of the nodule. Microscopic examination revealed the predominant cell type to be fibroblastic with vesicular lightly staining nuclei and eosinophilic cytoplasm. In the central region the cells were either plump and ovoid with an ill-defined eosinophilic cytoplasm and irregular reticulin fibres (*Fig.* 1), or spindle-shaped with a compact fasciculated pattern and a regimented arrangement of reticulin fibres. In the peripheral regions the cells were less compact. Only occasional mitotic figures were identified and none had abnormal features. The stroma was highly vascular, particularly at the periphery (*Fig.* 2), with many vascular clefts, and spaces separated the fibroblastic cells. Throughout the tumour red blood cells lay in endothelialized clefts and non-endothelialized intercellular spaces (*Fig.* 3). Occasional vessels were cuffed with sparse accumulations of lymphoid cells. A small amount of collagen was present; no multinucleated cells were identified. Apart from the fat cells at the edge of the nodule no lipid-containing cells were identified to suggest that the tumour had a lipomatous origin and the nodule had no features distinctive of a neurilemoma (no Antoni tissue type A and B and palisading).

Discussion

The term 'nodular fasciitis' is now generally accepted as an apt description of a peculiar lesion which is usually found in subcutaneous or deep fascial planes (Leading Article, 1973). The nodule is generally 1–3 cm in size and has distinctive histological features. It appears as a vascular proliferation of fibroblasts with a patchy lymphocytic infiltration, occasional islands of collagen and occasional giant or multinucleated cells (Price et al., 1961; Mackenzie, 1970). The cellularity of the lesion and the presence of mitotic figures have led to it being confused with a variety of mesodermal tumours and reactive processes, including sarcomas. It usually grows rapidly but it does not metastasize or recur if completely excised (Stout, 1961; Hutter et al., 1962).

Although known to occur in a variety of locations, including the orbit (Font and Zimmerman, 1966), it has not to our knowledge been described as an extradural tumour causing compression of the spinal cord. Analysis of spinal cord tumours in the past (Elsberg, 1941; Kernohan, 1941; Austin, 1961) has listed 'fibromata' as constituting less than 1 per cent of extradural neoplasms. Unfortunately the histology of these fibromata was not described. The origin of nodular fasciitis is still in doubt. Traumatic stimulus has been cited as a possible aetiological factor (Soule, 1962), but in the present case there was no history of trauma to the back. The unusual situation in this case raises the questions of dermal implantation (Manno et al., 1962; James and Lassman, 1972), but a lumbar puncture had not been performed previously. In subcutaneous tissues nodular fasciitis is relatively harmless, but in this case in the confines of the vertebral canal it caused spinal cord compression and paraplegia.

It is important to identify the lesion histologically because, despite its appearance, it is benign (Price et al., 1961; Hutter et al., 1962; Soule, 1962), and in the present case its removal at an early stage has prevented a permanent neurological deficit.

Acknowledgements

The authors wish to thank Professor John Hankinson under whom this patient was admitted, and Professor B. E. Tomlinson for verifying the histology of the tumour.

Peritoneal mesothelioma

P. S. F. CHAN, T. W. BALFOUR, J. B. BOURKE AND P. G. SMITH*

SUMMARY

Two patients with primary peritoneal mesothelioma are reported. They had abdominal symptoms, no symptoms referable to the respiratory system and normal chest X-rays. There was no clinical evidence of impaired respiratory function. One of the patients had a history of brief asbestos exposure over 20 years before diagnosis. The procedure for obtaining compensation is outlined and the protean uses of, and hence possible exposure to, asbestos are noted. In screening programmes consideration should be given to both pulmonary and abdominal symptoms. Laparoscopy may have a part to play in earlier diagnosis of peritoneal mesothelioma.

MESOTHELIOMA is a rare primary tumour of cells which line serosal cavities. It may arise from pleura, peritoneum or pericardium but the typical clinical presentation is as a thoracic or abdominal problem, yet occasionally both may be involved.

Initially, peritoneal mesotheliomas appear as whitish nodules scattered over visceral and parietal peritoneum which later coalesce to form plaques and masses. Characteristically, even with massive tumour growth and in the late stage of the disease, invasion of bowel or adjacent viscera such as liver is limited. As they grow mesotheliomas appear to encase the intraperitoneal contents. Multiple distant deposits do occur but metastasis is typical only to the regional lymph nodes.

Histologically, there is a wide spectrum of appearance varying from a predominantly epithelial pattern on the one hand to an almost pure spindle form on the other; a mixed epithelial and connective tissue pattern is not uncommon. Appearances can vary within a tumour and from patient to patient. The epithelial element may vary from well-differentiated tubules and papillae to solid epithelial formations. Some mesothelioma cells are vacuolated and contain mucin of connective tissue origin.

The criteria for the diagnosis of peritoneal mesothelioma were stated in 1960 by Winslow and Taylor to be: (1) a compatible clinical history, (2) characteristic gross features, (3) characteristic microscopic features and (4) progressive growth of the tumour in the characteristic manner resulting in the death of the patient. Since this report there has been a rising incidence of mesothelioma and this may in part be due to increasing awareness by pathologists (Moertel, 1972).

Patients with peritoneal mesotheliomas typically present with subacute intestinal obstruction and weight loss (Moertel, 1972). The commonest symptom is abdominal pain, while ascites is the commonest physical sign, being present in 90 per cent of cases (Moertel, 1972). A mass is occasionally found and nausea and vomiting are uncommon (Moertel, 1972). The onset of symptoms is insidious but once the diagnosis is made, death usually ensues within a year (Enticknap and Smither, 1964; Newhouse and Thompson, 1965; Smith et al., 1968).

The relationship between asbestos exposure and mesothelioma is well recognized, as is the long latent period of 20–47 years (Wagner et al., 1960; Newhouse and Thompson, 1965; Selikoff et al., 1965).

Two patients with primary peritoneal mesothelioma presented to the Professorial Surgical Unit in Nottingham during a period of just over 1 year and they are reported in detail below.

Case reports

Case 1: A 64-year-old man was admitted as an emergency on 18 February 1973 with a 5-hour history of colicky epigastric pain and vomiting. On examination there was tenderness in the right upper quadrant. A diagnosis of acute cholecystitis was made and he was treated conservatively. His symptoms and signs settled rapidly and he was discharged to outpatient care. A subsequent intravenous cholangiogram showed that the gallbladder contained gallstones. Five weeks later he was readmitted with an exacerbation of his symptoms. Urgent cholecystectomy was performed (27 March) through an upper right paramedian incision. At operation the pancreas was noted to be bulky and there were small white nodules on the omentum and parietal peritoneum which had the appearances of fat necrosis. Histological examination of the gallbladder showed severe chronic cholecystitis. He made a good recovery from operation and was discharged to outpatient care.

Three months after operation he noticed colicky pain around the scar which was aggravated by fatty foods and associated with vomiting. On examination he was found to have a large, irregular, non-tender, hard mass in the right hypochondrium. There was no ascites. He was readmitted on 21 September. He was noticed to have lost 19 kg in weight in the preceding 6 months. Plain abdominal X-ray showed a large soft tissue mass in the right upper quadrant which was displacing the small and large intestine. There were multiple small bowel fluid levels.

Laparotomy (23 September) was performed through the previous incision, and it was difficult to enter the abdominal cavity as in places the peritoneum was between 1 and 2 cm thick, rigid and like marble. There were multiple small white nodules throughout the peritoneal cavity and on the serosal surfaces of the intestine. The small bowel was subacutely obstructed. There was a minimal quantity of peritoneal fluid and some was submitted to bacteriological examination, including culture for tubercle bacilli. Biopsies were taken of serosal nodules and from the peritoneal mass. The diagnosis was uncertain and carcinomatosis was considered the most likely. The patient made a satisfactory recovery from operation.

No acid- and alcohol-fast bacilli were seen on Ziehl-Neelson staining or grown from the peritoneal fluid.

Histology of the biopsies (*Fig.* 1) showed nodular and diffuse infiltration by mesothelioma of a tubulopapillary pattern with clefts and papillae lined by plump epithelial cells with a fibromatous stroma. The nuclei of the epithelial and connective tissue elements were vesicular with prominent red nucleoli.

---

* University Department of Surgery and Department of Pathology, General Hospital, Nottingham.

After the diagnosis of mesothelioma the patient's chest X-rays were reviewed and no evidence of pleural plaques was found. He produced no sputum which could be examined for asbestos bodies. On further close physical examination there was no evidence of finger clubbing or clinical abnormality of his respiratory system. Inquiry into his occupational history revealed that during the Second World War he had fitted asbestos filter pads while assembling respirators. The histology slide of his gallbladder and further sections were reviewed and showed small islands of tissue suggestive of mesothelioma.

The patient was discharged home 3 weeks after operation without specific treatment. He slowly deteriorated and died on 17 February 1974. At autopsy he was emaciated. There were bilateral costal and diaphragmatic hyaline pleural plaques and the lungs contained asbestos bodies. The peritoneal cavity was almost completely obliterated by dense white tumour of up to 2·5 cm thickness on serosal surfaces. In some areas there were discrete nodules but the liver and spleen were encased in tumour. There was no evidence of a primary epithelial neoplasm. The post-mortem findings were in keeping with a primary diffuse peritoneal mesothelioma.

Case 2: A 75-year-old retired policeman with gout was first noticed in 1971 to have a mass in the left iliac fossa. Barium enema examination at this time showed a few diverticula in the descending colon. In May 1972 his general practitioner noticed that he was anaemic with gross ankle oedema and that the mass was still present in his left iliac fossa. He was referred to the Professorial Surgical Unit, Nottingham, for further investigation. The patient then volunteered that he had had intermittent attacks of left iliac fossa pain of about a week's duration since 1964.

Examination at this time showed that he was anaemic (haemoglobin 5 g per cent) with gross ankle and sacral oedema. His liver was enlarged and there was a large, mobile, slightly tender mass in the left iliac fossa. No ascites was detected. A barium enema examination showed an irregular extrinsic mass displacing the medial wall of the descending colon, and excretion urography showed a soft tissue mass indenting the bladder superiorly.

At laparotomy (23 May) there was a minimal quantity of free fluid. Numerous pedunculated tumours arose from the peritoneum and the serosal surfaces of the intestine. The largest was about 8 cm in diameter and was in the left iliac fossa. Multiple biopsies were taken.

Histological examination (*Fig.* 2) showed a solid and epithelial neoplasm with a mucinous and oedematous stroma. The tumour cells had voluminous cytoplasm and some were vacuolated. The features were those of peritoneal mesothelioma.

The patient made an uneventful recovery from operation, apart from an exacerbation of his gout which was rapidly controlled with phenylbutazone, and he was discharged home. His chest X-rays were reviewed and no evidence of pleural plaques was detected. Between September 1972 and July 1973 he was admitted to hospital three times for blood transfusion and twice with subacute intestinal obstruction which responded to conservative management. He died at home in July 1973 and a post-mortem examination was not performed.

After death, his family was interviewed and there did not appear to be any history of domestic or industrial exposure to asbestos.

Discussion

Much greater quantities of asbestos were used during and immediately after the Second World War than ever before. Since the recognition of the relationship between asbestos exposure and the development of mesothelioma (Enticknap and Smither, 1964; Newhouse and Thompson, 1965; Smith et al., 1968) Selikoff et al. (1965) have suggested that the occurrence of these neoplasms has and will continue to increase.

The 2 patients reported here contrast in their clinical presentation. *Case* 1 showed no symptoms typically associated with mesothelioma (Moertel, 1972) until after cholecystectomy when the overlooked intra-abdominal neoplasm grew rapidly and formed a massive tumour within a few months. Lazarus et al. (1971) reported a similar rapid development of an 8-cm mesotheliomatous mass in the left upper quadrant of the abdomen 6 months after laparotomy. *Case* 2 presented with insidious symptoms of several years' duration, and anaemia ultimately precipitated his full investigation. On clinical examination both patients had abdominal masses and neither had ascites. Reports in the literature (Winslow and Taylor, 1960; Enticknap and Smither, 1964; Smith et al., 1968; Moertel, 1972) have noted that ascites is common and masses are rarely found. It thus seems that awareness by surgeon and pathologist alike may be a major factor in making the diagnosis.

Abnormal chest X-rays are frequently found in asbestos workers who subsequently develop peritoneal mesothelioma (Mann et al., 1966; Borow et al., 1967; Smith et al., 1968; Roberts and Irvine, 1970). Of the 2 patients reported here, neither showed chest radiological abnormality in spite of *Case* 1 having pleural and diaphragmatic plaques at autopsy and a history of brief asbestos exposure.

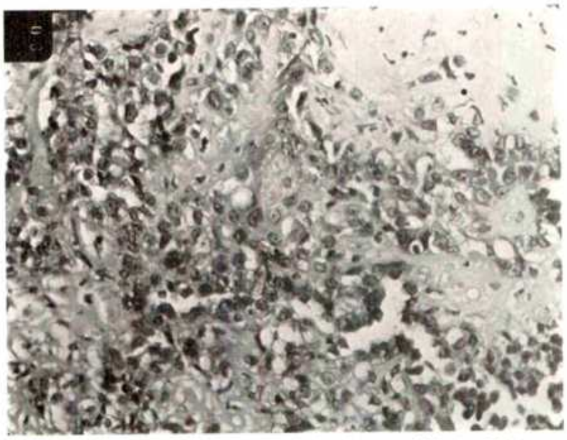

Fig. 1. *Case* 1. Mesothelioma of mixed type. HE. (× 220.)

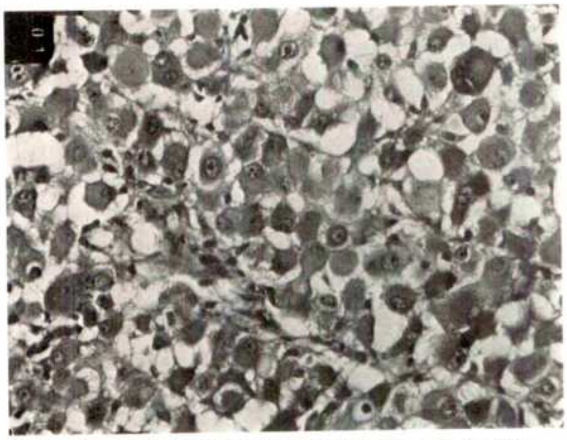

Fig. 2. *Case* 2. Epithelial type mesothelioma. HE. (× 250.)

Special laboratory investigations are unhelpful in diagnosis, and radiology offers little specific aid apart from excluding gross pleural involvement or showing small flakes of calcification in diaphragmatic plaques (Borow et al., 1967; Moertel, 1972). Extrinsic pressure or encasement of part of the gastro-intestinal tract by tumour may be seen on barium investigation but the findings are non-specific (Lazarus et al., 1971).

On histological examination vacuolated epithelial elements are seen, but their contents do not stain like epithelial mucin. However, the contents of the vacuoles may be demonstrated with metachromatic stains such as thionin, and the major substance present is hyaluronic acid (Winslow and Taylor, 1960). Metachromatic staining within the tumour and its removal by hyaluronidase is thus strong evidence for the diagnosis of mesothelioma (Winslow and Taylor, 1960; McCaughy, 1965). Kannerstein et al. (1973) have noted that histochemical methods will not resolve all the problems in the histological diagnosis of mesothelioma but they do have a supporting role. However, it is in patients where diagnosis is difficult that the possibility of a positive reaction to histochemical staining is least likely. Ascitic and pleural fluid should be routinely screened for hyaluronic acid, as this may be found with mesothelioma (Harrington et al., 1963). However, Boersma et al. (1973) have shown that the presence of hyaluronic acid in tissue fluid is not specific to mesothelioma and may occur with other cancers. They concluded that the presence of hyaluronic acid in effusions or tissue biopsies should be one criterion for the diagnosis of mesothelioma which was useful when histology or pathology was equivocal. It should be remembered that Spicer et al. (1967) have referred to the lack of identity in histochemical and biochemical characterization of the mucopolysaccharides. Butler and Berry (1973) have reported that malignant mesothelioma may be diagnosed by exfoliative cytology. This depends on the recognition of cells which show the cytoplasmic differentiation of mesothelial cells and have nuclei with the usual criteria for malignancy. In patients with peritoneal mesothelioma this technique may be of value as the commonest physical sign is ascites (Moertel, 1972). Peritoneal fluid obtained at laparotomy should also be examined by this technique. The specimens should be divided into two and part placed in a dry sterile container and the remainder into a citrated bottle for making suitable cytological preparations.

Laparoscopy, biopsy and exfoliative cytology may have a place in early diagnosis if suspicion is high. However, this may only occur if an appropriate industrial history of asbestos exposure or contact is obtained. This may not always be possible, for only one of our patients had such a history. Biopsy specimens from suspicious tumours should also be taken into alcohol fixative so as to preserve the water-soluble hyaluronic acid which forms a large part of the mucin produced by a mesothelioma. If specimens are placed in formalin fixative hyaluronic acid may be lost from the tissue and cytoplasmic vacuoles may appear empty (Harries et al., 1973).

Treatment is unsatisfactory, as is shown by the survival from diagnosis to death being typically less than 1 year (Enticknap and Smither, 1964; Newhouse and Thompson, 1965; Borow et al., 1967; Smith et al., 1968; Moertel, 1972). However, it should be noted that *Case* 2, who did not have a history of industrial exposure, survived for 14 months. Systemic, intrapleural and intraperitoneal cytotoxic therapy and radiotherapy have all been used with little success (Moertel, 1972). This may in part be due to the lesion presenting at an advanced stage when a large tumour mass is present. It is tempting to speculate what might have been achieved in *Case* 1 if cytotoxic therapy had been prescribed if the diagnosis had been made after cholecystectomy as at that stage the tumour mass was small.

At present the relatives of a patient with mesothelioma become eligible for compensation if asbestos or asbestos bodies are found in the lungs with or without pulmonary fibrosis. Death is reported to HM Coroner who may order an autopsy and also hold an inquest. The findings are reported to the Pneumoconiosis Panel and compensation may be awarded. At autopsy it is important to exclude a gastro-intestinal neoplasm. Elmes and Wade (1965), Selikoff et al. (1968), McDonald et al. (1970) and Selikoff et al. (1973) have reported excess mortality from gastric, colonic and rectal carcinoma in groups of asbestos workers. However, Newhouse (1973) is of the opinion that the evidence for this increased risk is inconclusive.

In patients dying from mesothelioma without an appropriate industrial history HM Coroner should still be informed so that an autopsy can be performed, as only in this way may the asbestos be identified and compensation obtained for the relatives.

It seems that asbestos will continue to be widely used commercially as this mineral breaks down on crushing into fibres which have great tensile strength and excellent thermal and electrical insulating properties. Asbestos fibre can be spun and used to make safety curtains and clothes. It may be used to form asbestos cement for insulation or protection from corrosion by substances such as sea water and acid, or it can be added to plastics to produce insulating materials. In this country exposure to asbestos is greatest in those employed in processing asbestos, and primary manufacturers take extensive safety measures (*Asbestos and Your Health*, *Working with Asbestos*; Howard, 1974; *Health and Safety at Work*, 1974). There is also much casual exposure to asbestos, such as when asbestos building board is sawn up where typically no precautions are taken and the worker is probably unaware of any health hazard (Martin, 1970). The building board itself is not the hazard, but asbestos is released into the atmosphere for inhalation by the worker when the sheeting is sawn up (Martin, 1970; *Health and Safety at Work*, 1974). The abandon with which asbestos lagging is ripped from pipes as buildings are refurbished contrasts with the strict care taken in HM Dockyards when asbestos lagging is removed and replaced (Elmes, 1966; Harries, 1968; *Health and Safety at Work*, 1974).

Persons employed by primary asbestos users have serial lung function tests and chest X-rays performed to assess the development and prognosis of asbestosis (Harries, 1968; Mackenzie, 1971). Those with repeated random exposure to asbestos, such as building workers, are typically not screened for the development of asbestosis, and ongoing medical surveillance would probably be impossible because the mobility of the labour force is high. In addition, the latent period for the development of mesothelioma is typically between 20 and 35 years (Enticknap and Smither, 1964; Newhouse and Thompson, 1965; Smith et al., 1968). This further emphasizes the importance of taking an adequate and detailed industrial history.

The 2 patients reported here had only abdominal symptoms, normal chest radiology and no routine clinical evidence of impaired respiratory function, although sophisticated studies were not performed. In screening asbestos workers consideration should be given to both pulmonary and abdominal symptoms. It may be that laparoscopy in appropriate patients could play an important part in earlier diagnosis and this may make the lesion amenable to therapy and thus improve the present dismal prognosis.

The negative cholecystogram in gallbladder disease

D. R. K. REID AND I. M. ROGERS*

SUMMARY

Seventeen cases of radiologically negative gallbladder disease are presented. In all it was possible to explain the symptoms on the basis of the 'disappearing stone' hypothesis. It is suggested that cholecystectomy should be advised in such patients provided that the symptoms are sufficiently characteristic and sufficiently severe.

THERE is a general assumption that the diagnosis of gallbladder disease should, in all instances, rest on the cholecystogram. It is the purpose of this paper to advance the proposition that biliary colic, implying gallstones, occurs with a clinically significant frequency when the cholecystogram is normal.

It is our impression that most surgeons (and practically all physicians) would demand positive X-rays before advising surgery, whereas we believe that the clinician should be prepared to advise cholecystectomy despite a negative report if he is convinced that the symptoms are sufficiently typical, sufficiently severe and sufficiently persistent.

Patients

Seventeen patients are presented. They are characterized by typical, severe and recurrent biliary colic, negative cholecystography on at least one occasion and complete relief of their pain after cholecystectomy.

Incidence

Most of these patients have occurred in the practice of one of us (D. R. K. R.) over a period of 10 years, during which 40–50 cholecystectomies have been performed annually. They therefore represent a small (approximately 3 per cent) but none the less interesting and important group.

Age and Sex

There were 2 males and 15 females with ages ranging from 21 to 70 years (average 43 years).

Symptoms

The *duration* of symptoms ranged from 6 months to 25 years with an average duration of 7·5 years. In every case there was a period of observation lasting at least some months before a final diagnosis was made and surgery advised.

Pain was the main symptom in all the cases and was a prerequisite for inclusion in the series. The pain was of a typical nature and distribution with severe and recurrent attacks which lasted from several hours to several days. Patients in whom a psychosomatic disorder or emotional instability was suspected were not included.

Radiographic findings

On at least one occasion a normal cholecystogram had been reported in each patient. The cholecystogram had been repeated several times in 6 patients, and in 3 instances a normal intravenous cholangiogram had been obtained. One patient had one normal cholecystogram and one normal intravenous cholangiogram (*Table* 1).

The cholecystogram was reported as abnormal on one occasion in 4 patients. In 2 patients normal findings on cholecystography became abnormal (radiolucent filling defects) over periods of 5 and 11 years respectively, while the symptoms remained the same. The remaining 2 patients had an abnormal cholecystogram initially but normal findings were reported after periods of 3 and 9 months respectively (*Table* 1).

Jaundice

Transitory jaundice had occurred in 5 patients, and in 1 six times. Two of these patients had a few cholesterol stones in the gallbladder, 1 had biliary mud and 2 had no stones at operation.

Three patients developed dark urine and pale stools during or soon after an attack of typical pain. This clinical state has been described as 'subclinical' jaundice, and it is interesting to note that it occurred both in patients with and without stones at operation (*Table* 1).

Stones

There are few differences between the 9 patients with stones and the 8 patients without stones at operation (*Table II*). The frequency of jaundice and the incidence of cholecystitis are nearly the same. Both groups were totally relieved of their attacks of pain by cholecystectomy, and the postoperative follow-up period is similar.

In 3 patients the stones were of mixed type, and in 2 of these the cholecystogram findings changed from normal to abnormal over periods of 5 and 11 years respectively. In 1 case biliary mud rather than stones was found, and in the remaining 6 the stones were small and yellow, measured 2–3 mm in diameter and numbered no more than 2 or 3 in any one case. They were obviously of cholesterol composition. The stones were usually within the gallbladder, but in one instance a small stone was removed from the cystic duct. Duct stones were not found despite 4 duct explorations.

Table II: PRESENCE OR ABSENCE OF STONES AT OPERATION

	Stones	No stones
Number of cases	9	8
Clinical or subclinical jaundice	4	3
Cholecystitis on histological examination	9	6
Follow-up (yr)	3·0	2·15

Pathological findings

The gross appearance of the stone-containing gallbladder at operation was usually within normal limits. Histological appearances varied from minimal to mild cholecystitis. All the patients with stones showed inflammatory change and all but 2 of the patients without stones at operation showed similar changes (*Table II*).

Follow-up

Freedom from attacks of pain was immediate and complete in all the patients over periods ranging from 6 months to 10 years (average 2 years 9 months). Most patients were eating freely and taking fat. Few clinicians would dispute that when a stone-containing gallbladder is removed from a patient suffering from attacks of biliary colic the attacks of pain are likely to cease. What is of interest in our series is that patients without stones at operation are similarly relieved of pain over a comparable follow-up period (*Table II*).

Discussion

Before operation the whole group was clinically indistinguishable, but subsequently they may be divided into those with and without stones in the gallbladder. In the former the calculi were of cholesterol and few in number, suggesting that the patients suffered from lithogenic bile (Small, 1968). In the latter the frequency of jaundice or subclinical jaundice and the postoperative freedom from pain make for the belief that stones previously present had migrated down the biliary tree and been expelled (Addleman, 1962; Gray, 1974).

Both situations are supported by evidence from other reports. Normal cholecystography has been associated with the finding of stones at operation (Large, 1968), and in patients with typical biliary colic the removal of an acalculous gallbladder has relieved pain (Mackey, 1934; Valberg et al., 1971; Gunn, 1973). In the acalculous patients both biochemical evidence of obstructive jaundice and structural abnormalities of the gallbladder have been common.

The significance of the histological appearances of cholecystitis is uncertain. When present it might suggest that stones have previously been in the gallbladder; when absent metabolically formed stones as former residents are not excluded.

We have based our diagnosis and also our hypothesis that this clinical group of patients is composed of those who have stones in the biliary tree which come and go entirely on clinical grounds. Provocation of an attack of pain with cholecystokinin is said to be of help in establishing a diagnosis of pain of biliary origin (Cozzolino et al., 1963; Valberg et al., 1971). We have used this test in some of our patients and have reported upon it previously (Reid et al., 1975). However, we feel that the clinical evidence is such that the clinician should be willing to make a diagnosis of gallbladder origin for pain and to recommend cholecystectomy in spite of negative X-rays when there is typical biliary colic, when all other causes have been excluded and the symptoms are severe. His decision would be supported by clinical or biochemical evidence of obstructive jaundice. In all instances an adequate period of observation should be allowed extending to months or, as with some individuals in our series, to years. Only in this way will the clinician become convinced of the need for operation.

Acknowledgements

We would like to thank Mr Tom Menzies, Consultant Surgeon, Glasgow Royal Infirmary, for permission to include one of his patients in our series and also Mr John Hutchison for permission to report on 2 patients under his care.

Reviews and notices of books

Chirurgie

P. A. A. Klok. 243×167 mm. Pp. 474+xi. Illustrated. 1974. Amsterdam: De Erven Bohn BV. No price given.

A PATIENT referred to a specialist will often ask the opinion of his general practitioner on suggested surgical treatment. This book, written in Dutch, aims to bring the general practitioner up to date on the recent developments in the surgical field. The author gives a survey of general surgery including traumatology, orthopaedics, urology and cardiovascular surgery. In some ways the book is comparable to Taylor and Cotton's *Short Textbook of Surgery*, although less attention is given to the pathophysiological basis of diseases. It combines the advantages and disadvantages of being written by one author. On the other hand, a comparatively complete survey of the Dutch surgical literature of the past 10 years is obtained.

H. MULLER

Vascular Surgery. Volume I. Peripheral Arterial Diseases

John J. Cranley, Cincinnati. 254×200 mm. Pp. 282+xvi. Illustrated. 1972. London: Harper & Row. £11.

THE author is to be complimented on the lucid format and easily readable style of this interesting and informative book. Whilst written on the basis of personal experience due recognition is readily accorded to the work of others, and appropriate references are provided at the end of each chapter.

The subject matter is well chosen and comprehensively covered, but the commentary is concise and to the point with a clear exposition of essential principles. Clinical common sense coupled with sound practical advice permeate the work and experienced surgeons will readily recognize familiar problems. This sense of empathy adds to the enjoyment of the book and the counsel proffered may hopefully dissuade younger surgeons in training from making similar mistakes. The standard of presentation is uniformly high throughout and all the chapters can be perused with profit, those on aneurysmal disease being especially good.

All these features together with the clarity of the illustrations combined with good photography and excellent angiographic reproductions have produced a book which it is a pleasure to recommend to all surgeons with an interest in this subject.

G. SLANEY

The Liver and Its Diseases

Fenton Schaffner, Sheila Sherlock, and Carroll M. Leevy. 180×250 mm. Pp. 353+xi, with 159 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.129.

THREE invited contributors have compiled this book discussing their own specialized interest in liver disease. Not one of them is a surgeon so the emphasis is on the medical and biochemical aspects of the damaged liver. The book is dedicated to Hans Popper on his seventieth birthday and begins with an appropriate citation of Popper's work followed by a short so-called 'philosophic statement' on hepatology in 1974.

There are chapters on the electron microscopic ultrastructure of the liver, the liver's handling of drugs, protein synthesis, bilirubin metabolism, the virology of hepatitis and liver biopsy.

In the middle of the book is a short, rather interesting, account of the history of treatment of liver disease called inappropriately 'Liver Therapy' since it does not discuss any treatment with the whole liver or its extracts. There are some fine illustrations of some of the early hepatologists, including Francis Glisson, and a remarkable picture of the so-called 'corset liver' showing the anatomical distortion produced by the fashion of 'wasp waists'. The book then returns to biochemistry, this time of the hepatitis B antigen. There are further chapters on hepatitis and hepatotoxicity due to drugs, including alcohol. The hepatorenal syndrome is treated rather superficially. There is quite an interesting article on the management of portal hypertension, but since it is compiled by a physician the surgical difficulties encountered in operating on patients with liver failure, coagulation defects and gross portal hypertension have not been given sufficient emphasis. Prophylactic portacaval shunts are condemned, and it is pointed out that the survival of patients with a therapeutic shunt is little improved compared with that of untreated patients. The author does, however, come out in favour for certain therapeutic shunts. Cancer of the liver gets half as much space as Wilson's disease.

The book will no doubt be of interest to physicians treating liver disease but has very little of value for the practising surgeon. When the physicians have failed and the patient is dying of liver disease, a new liver would seem to be a logical form of treatment, yet liver transplantation does not even appear in the index!

R. Y. CALNE

Hair Transplant Surgery

O'Tar T. Norwood, Oklahoma. 255×170 mm. Pp. 108+xiii, with 69 illustrations. 1973. Springfield, Ill.: Charles C. Thomas. $10.50.

JUDGING by the present spate of inquiries about hair transplants, this book will interest dermatologists and plastic surgeons, whether or not they actually intend to carry out hair transplant procedures. However, the author warns the reader that the instruction in the book is insufficient for him to practise hair transplants without either joining a formal training programme or observing the procedure.

The monograph commences with a practical (if rather complex) classification of male pattern baldness. It covers comprehensively the selection of cases, the technique of hair transplant surgery and the complications. There is a discussion on the best size of graft to use, and the results of a questionnaire sent to those practising hair transplants about their technique and complications are included. There is a short final chapter reviewing the research in the use of hair-bearing homographs.

The use of the author's technique in alopecias other than male pattern baldness is briefly mentioned. More information would have been welcome here but perhaps the brevity reflects the relative lack of success.

The book is well illustrated, demonstrating the technique of hair transplants in detail, and there is a colour section containing 64 pictures of patients before and after treatment.

B. D. G. MORGAN

Surgical Aspects of Haemodialysis

P. R. F. Bell, Leicester, and K. C. Calman, Glasgow. 234×153 mm. Pp. 130+xii. Illustrated. 1974. Edinburgh: Churchill Livingstone. £4·50.

THIS book has been carefully thought out and is written in a style which is clear and easy to read. Points such as the preparation of the patient and anaesthetic techniques have not been forgotten, and the descriptions of surgical procedures are clear enough to be followed readily. The line drawings are simple and informative, though one is left with a wish for more coloured plates. There is a detailed bibliography related to each procedure which in itself makes a valuable contribution.

The authors have not entered into any discussion on the prevention of complications and how they affect the responsibility of the physician in relation to these surgical aspects of hemodialysis.

The volume is compact and concise. It will be invaluable to the student in this field and is likely to be regarded as a most useful practical manual by those gaining experience of practical work in this speciality.

ROSEMARIE BAILLOD

Atlas of Vascular Surgery

Robert R. Linton, Boston. 310 × 240 mm. Pp. 504 + xviii. Illustrated. 1973. London: W. B. Saunders Company. £27·65.

THIS expensive and lavishly produced work based on the personal experience of an internationally acknowledged master vascular surgeon disappointingly fails to measure up to expectation.

Both the introduction and part 1, dealing with diseases of veins, are strikingly devoid of modern methods of assessment. The section on thrombo-embolic disease is especially poor in this respect, for the radiofibrinogen uptake test, Doppler scanning and the prophylactic effect of subcutaneous heparin, to mention but a few, are not even mentioned. The views expressed regarding management and the vigorous advocacy of venous interruption will certainly not find general acceptance among surgeons in this country.

By comparison, the sections in part 2, dealing with arterial disease, are of high standard, containing an abundance of practical points, invaluable to the tyro and inducing a sense of *déjà-vu* in the experienced. The portions on aortic aneurysmal disease are easily the best in the entire work though even here minor points of contention exist; for example, few surgeons now advocate complete removal of the aneurysm. The management of aorto-iliac occlusive disease is very adequately dealt with, but many would not share the author's opinion that aortography is seldom indicated, or his strong condemnation of the bypass principle without division of the aorta because of the risk of graft thrombosis.

The saphenous vein bypass for femoropopliteal disease is well described, though some aspects of technique are at variance with those generally accepted. Few British surgeons would agree that total removal of a popliteal aneurysm and its accompanying vein is either wise or necessary, or that superficial femoral vein ligation at the groin should be performed as a preliminary to low thigh amputation to prevent subsequent pulmonary embolism.

In the section on cerebrovascular insufficiency, disease of the brachiocephalic trunks is dismissed on one page and the value of bypass procedures for multiple lesions and in poor risk patients is not discussed. Carotid endarterectomy is well described but techniques for vertebral artery insufficiency are not mentioned.

It is regrettable that some portions of this atlas are disappointing because the remainder contains much worthwhile practical advice, especially for young surgeons in training. The standard of the colour illustrations is high but their number could be reduced without detriment. The corresponding reduction in cost might be an important consideration in a book currently priced at £27·65.

G. SLANEY

Roentgen Examinations in Acute Abdominal Diseases

J. Friemann-Dahl, Oslo. Third edition. 230 × 150 mm. Pp. 617 + xiv, with 432 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. $29.50.

THE third edition of this book which now appears 14 years after the previous one carries the same stamp of authority that characterized the original work. So much of our knowledge of the radiological interpretation of the acute abdomen has stemmed from this author that it is perhaps hard to realize that much of the information that is now accepted as commonplace was included as original observations in the first edition.

The hospital where the author practised was orginally responsible for much of our knowledge of plain radiography and, more recently, of abdominal aortography, and it is gratifying to see in this new edition the appropriate attention being given to this newer method of examination. Perhaps in the United Kingdom the value and potentiality of arteriography in acute abdominal vascular conditions and in closed abdominal trauma are not yet fully realized.

Throughout this book the superb quality of the radiographs stands out and there is no doubt that many of the errors of interpretation that occur are the direct results of attempts to interpret films of inadequate quality. Perhaps some of the illustrations where the original blocks have been retained show some loss of their original crispness.

In acute abdominal emergencies it is unfortunate that expert radiological assistance which always should be available is often not consulted, as although the dramatic signs of perforation and obstruction are usually easily recognized the finer and less obvious features which may be vital are not appreciated. This book presents an authoritative and detailed study of these features which would well repay serious study.

A few statements that have been carried on from earlier editions such as 'the importance of fluoroscopy in chest conditions' could well be edited from future editions, and the too frequently occurring spelling errors unreasonably detract from this excellent book.

Besides the value of this authoritative book to radiologists, it should be readily available for reference in any emergency department where radiological investigations of the acute abdomen are made.

The publishers of the book maintain an excellence and quality in keeping with their other productions for which they have gained universal acclaim.

ERIC SAMUEL

Surgical Technology. Basis for Clinical Practice

Mary Louise Hoeller, St Louis, Missouri. Third edition. 245 × 170 mm. Pp. 386 + xii, with 295 illustrations. 1974. London: Henry Kimpton. £5·20.

BRITISH readers may be puzzled by the title. The previous two editions were entitled *The Operating Room Technician*, which is more explicit to us. The book describes modern American views on the organization, training and practice in the operating theatre. The changed title is intended to reflect the response of theatre staff to technical advances in surgical procedures.

To the surgeon the book presents a hotch-potch of anatomy, operative detail, theatre equipment, anaesthetic and radiological techniques, sterile trolley layouts, legal requirements, patient handling and theatre organization. However, at a time of readjustment within the Health Service, when operating theatre resources are overstretched, progressive American views on the total running of theatres is of great interest to those involved in planning and administration. This book offers a stimulating view of the theatre to those working full-time as nurses and technicians. To the surgeon it displays the careful organization and training behind the efficient scrub-nurse handing him instruments.

R. M. KIRK

Cardiovascular Applications of Ultrasound

Edited Robert S. Reneman. 240 × 165 mm. Pp. 462 + xv. Illustrated. 1974. New York: American Elsevier Publishing Company. $28.90.

THIS book contains the proceedings of an international symposium held in Belgium in May 1973. As the editor points out, the importance of ultrasound in cardiology, cardiovascular physiology and pharmacology is growing fast, and the contributors to this book include a number of the most active investigators in the field.

In part 1 ultrasonic Doppler flowmeters are dealt with from the point of view of instrumentation and theory. This section includes a discussion on possible harmful biological effects, the problem of noise and the functional limitations of the Doppler flowmeter, methods of display and computation and the problems of quantification. In the next sections the uses of transit time instruments to measure organ dimensions and small volume displacements are described, and there follow two sections on the experimental and clinical applications of catheter tip velocity probes and the effects of vascular curvatures and stenoses on the velocity profile. The clinical applications of Doppler instruments in cerebral vascular disease, for coronary artery blood flow measurements, in peripheral arterial disease, in venous disease and for the non-invasive recognition of heart disease are fully discussed.

In contrast to the 389 pages devoted to Doppler ultrasound, flow measurement and experimental applications, the use of pulsed echo for cardiac diagnosis occupies less than 50 pages. Since many would consider this to be the most important and exciting development of ultrasound, the uneven weighting is disappointing to say the least. The section contains only descriptions of two new experimental devices, electro-scan and multi-scan echocardiography, followed by a short section by Edler, the pioneer of cardiac echocardiography, and an even shorter section by Bopp, one of the most active investigators in this field. The final section is a general discussion on the use of Doppler instruments in vascular surgery, on ultrasonic imaging, on venous contamination as a source of error in transcutaneously recorded arterial flow velocities and, strangely, on the determination of myocardial wall thickness by ultrasonic means. These rather disjointed themes have apparently emerged from the final discussion at the end of the symposium.

This book, containing so much which was merely of passing interest at the time when it was discussed, so much which was evolutionary and rapidly changing and so unevenly weighted between flow measurement and ultrasound for cardiac diagnosis, has little to commend it for vascular surgeons or cardiologists wishing to learn more of the techniques, applications and range of cardiovascular ultrasound. It is likely to prove of most value as a momento to those who attended what must have been a stimulating conference on ultrasonic flow measurement. Since the vascular applications of ultrasound are dealt with almost to the exclusion of the cardiac applications and since much of the content concerns theoretical and developmental aspects, the book is likely to find only a limited readership and certainly does not justify its title.

C. OAKLEY

Acupuncture for Physicians

Teruo Matsumoto, Philadelphia. 246×175 mm. Pp. 204+ix, with 148 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. $14.75.

THE object of this short book is to provide sufficiently detailed information for the practising qualified medical practitioner so that he could be in a position to advise his patients on the confused subject of acupuncture, and by his advice perhaps prevent premature and even disappointing results.

The book is divided naturally into three parts by its emphasis on different aspects of acupuncture. The first few chapters deal with the classic acupuncture points, and it is refreshing to see a break from traditional Chinese terminology, in that Professor Matsumoto has produced his own set of anatomically based terms for the median points corresponding to the emerging peripheral nerves. The next few chapters deal with the symptomatic treatment of certain arthritic conditions in an empirical fashion, but with a well-designed protocol. There are no claims made for the reversal of the basic pathology, only symptomatic relief being claimed in the cases described. The third part sets out protocols for biological research work which has to be done in the future to show the efficacy of the procedure in different areas of acupuncture therapy. There is only scant reference to acupuncture anaesthesia, since the author has no practical experience of this subject.

On the positive side of this book, Professor Matsumoto carefully describes experimental conditions and data, even including a detailed description of the apparatus used, so that his work could be repeated or even pre-empted. On the negative side, one is left to wonder if acupuncture really works, and if the objective of the book is to help the doctor advise the confused patient on acupuncture this would be difficult based on reading this book alone. It would be an exceptionally good book on the bookshelf of those interested in experimental acupuncture.

IAN CAPPERAULD

Medical and Surgical Emergencies

Edited John H. Schneewind (deceased), Illinois. Third edition. 175×110 mm. Pp. 434+x. Illustrated. 1973. London: Lloyd-Luke (Medical Books) Ltd. £4·25.

THIS manual was designed originally for use at the University of Illinois hospitals and was initially privately printed. Quite properly, it was considered that it deserved a wider distribution. The third edition has been produced after considerable revision and a change of format for easy readability and quick reference.

The range of emergency situations covered by this manual is far more extensive than its simple title suggests. In addition to the chapters that one would expect in a book bearing this description, there are contributions on, for example, otolaryngologic, ocular and proctologic emergencies. Excellent editing of excellent contributions has produced an informative and well-balanced manual which recognizes all aspects of emergency situations. This is a book designed for both preparation and practice. It should be available in every accident and emergency department and, since it fits very well into the pocket of a white coat, should be a constant part of any casualty officer's equipment. However, its usefulness is not confined to hospital and it is to be recommended to anyone who has to deal with emergency situations occurring in any circumstance. Considering the extent to which this manual is likely to be employed, preliminary reinforcement of the soft covers would be advisable.

D. M. PROCTOR

Flexible Implant Resection Arthroplasty in the Hand and Extremities

Alfred B. Swanson, Michigan. 260×180 mm. Pp. 352+xv, with 552 illustrations. 1973. London: Henry Kimpton. £16·85.

THERE is more to this book than the title would suggest. It is really a treatise on the surgery of rheumatoid arthritis in the arm and hand. It opens with an account of the development of silicones, then leads into a detailed description of the evolution and testing of flexible implants.

Evaluation of results is of vital importance and there is a comprehensive chapter on recording deformity, disability and subsequent improvement after surgery. The large part played by extra-articular deforming forces is stressed and the subsequent need for intensive postoperative splinting emphasized.

The content of the book is rather patchy. There are excellent sections such as evaluation but there are also poor sections. For instance, there is a simple description of the pathology of rheumatoid arthritis, which is surprising in a book concerned with the surgery of the disease. Similarly, the results of finger prostheses are discussed in great detail but those of carpal replacements are rather nebulous.

The book concludes with an extensive bibliography. It is an interesting book reflecting a lifetime's work by Dr Swanson. It should be read by all orthopaedic surgeons and by anyone concerned with the development of implants.

B. A. ROPER

Cryosurgery in Urology: International Symposium in Stuttgart, 1973

Edited H. J. Reuter. 230×155 mm. Pp. 109+ix, with 56 illustrations. 1974. Stuttgart: Georg Thieme Verlag. No price given.

WHEN cryosurgery first attracted the attention of urologists it was for the hope it seemed to hold out of affording a simple and safe means of dealing with urinary obstruction in very old and very unfit men for whom conventional forms of surgery were too dangerous. It was not long before the complications of the treatment were recognized, and to avoid them it became necessary to introduce more and more elaborations on the originally simple theme. The enthusiasts who contributed to this symposium discussed in detail some of these modifications. The bladder may be filled with helium to avoid freezing its wall and the orifices of the ureters; several thermocouples may be introduced per rectum or perineum to monitor the spread of the ice-ball, or the process may be observed through a suprapubic cystoscope. The problem of getting rid of the once-frozen slough may be overcome by performing an endoscopic resection either at the same time as the freezing or a few days later. All of which must make one wonder why endoscopic surgery is not carried out in the first place, and it may be significant that the last section of the symposium is given over to some aspects of transurethral resection which appear to have struck the participants as being new. The outstanding and indeed the most exciting feature of cryosurgery is the hope that it may somehow modify the body's immunological defences against prostatic, and perhaps bladder, cancer. For those who wish to be brought up to date this is a useful and informative symposium which deserves careful study.

JOHN BLANDY

Microbes and Man. A Laboratory Manual for Students in the Health Sciences

Isabel J. Barnes, Sangamon State University, Harry W. Seeley, jun., Cornell University, and Paul J. Van Demark, Cornell University. 275 × 215 mm. Pp. 203 + vi, with 79 illustrations. 1974. Reading: W. H. Freeman & Co. £2·40.

THIS manual is written for students in courses related to nursing and health care.

The authors state that 'a knowledge of basic laboratory techniques of microbiology will serve them well'. In Britain training in laboratory technique is generally considered to be irrelevant except to medical laboratory workers who might find this a useful introductory manual. Nurses armed with culture plates and swabs and guided by a bacteriologist can demonstrate environmental contamination and can test the efficacy of cleaning and sterilization methods; no training in laboratory technique is required. A knowledge of purification methods, identification tests and the use of the microscope will not help them.

This condensed version of a course for professional microbiologists should to be tailored to meet the needs of a different audience. A serious omission is failure to mention any method for testing the efficiency of an autoclave.

E. J. STOKES

Quick Reference to Surgical Emergencies

Edited Gerald W. Shaftan and Bernard Gardner, New York. 235 × 162 mm. Pp. 664 + xvii. Illustrated. 1974. Oxford: Blackwell Scientific Publications. £11·90.

THE editors of this large volume anticipate that it will meet the needs of 'family physicians, emergency physicians, nurses and paramedical staff'. There is a remarkably detailed coverage of every conceivable surgical emergency. Some general chapters, e.g. 'Fluid and Electrolyte Problems', can be read in isolation and provide helpful surveys. Bone and joint injuries are dealt with clearly and each can be referred to quickly. It is less easy to turn up specific abdominal and thoracic emergencies and the diagnosis of these is covered very sparsely. For many conditions, e.g. renal injuries, there are long lists of ancillary investigations, but little indication as to which are the most pertinent and which readily available in the average hospital.

Trainees in surgery or accident work would find it difficult to get balanced views on many of the topics covered, and paramedical staff might only be confused by the elaborate instructions given. However, this is a remarkable 'encyclopaedia' (although the editors deny an intention to produce this!). It is written by acknowledged experts working as a team in one of the busiest hospitals in New York. The book is recommended strongly for the library of the accident and emergency department of all large hospitals but not as a textbook for the surgical trainee. What a pity that in the United States the use of the word 'débridement' is even more confused than with us!

JOHN SHEPHERD

Advances in Cardiovascular Surgery

Edited J. W. Kirklin, Alabama. 234 × 160 mm. Pp. 279 + xiv. Illustrated. 1973. New York: Grune & Stratton. £7·45.

THIS is an excellent and important book which should be on the shelf of every surgeon and physician cardiologist interested in current thought and progress in cardiovascular surgery.

About two-thirds of the book is devoted to congenital heart disease, and this is appropriate as representing the growing edge of advances in the field, with particular emphasis on infant surgery. The remaining sections deal perfectly adequately with valvular heart disease and the important and advancing but less intellectually demanding field of ischaemic heart disease.

As the editor of an outstanding team of contributors, Kirklin's own contributions stand out. Although his somewhat complex classification of congenital heart disease may not be to everyone's taste, it has been widely accepted not only by some of the contributors but by a large number of active surgeons. The section on infant surgery by Kirklin's group is full of important basic principles, but again tends to be too detailed and tabulated and out of character with the rest of the book.

Hard factual data are presented with no woolly statements and, in this respect, it sometimes reads more like a series of scientific publications than a textbook. The reader will, however, appreciate the clear bold sectional subheadings and the good quality of the illustrations, although that on p. 59 appears to be inverted, and on p. 60 the ventricular septal defect is labelled 'D' instead of 'V' which appears in the legend.

In the section on acquired valvular disease an important chapter deals with myocardial protection and function during open heart surgery, and although it does not resolve this current controversy seems to come down on the side of coronary perfusion and the avoidance of prolonged induced ventricular fibrillation.

A great deal of important information is contained in this book and it represents a ready source of current thought and knowledge together with detailed and down-to-earth technical detail. Like many other transatlantic books it is comparatively expensive. However, it would be difficult and laborious to assemble this information from the journals, so that it represents an important volume for all doctors actively engaged in this field.

DONALD ROSS

Handbook of Orthoptic Principles

G. T. Willoughby Cashell and Isobel M. Durran. Third edition. 215 × 135 mm. Pp. 137 + x, with 29 illustrations. 1974. Edinburgh: Churchill Livingstone. £2·25.

The purpose of this book is to provide a handbook on orthoptics for ophthalmologists, an aim which it achieves well besides giving an outline of orthoptics. The book is divided into twelve chapters and gives a useful introduction to the subject of strabismus and anomalies of binocular vision, together with their diagnosis and treatment. Briefly and clearly written, the text contains the basic information essential to the understanding of the subject, but its brevity leaves much detail unmentioned—a feature which makes it inadequate for most orthoptic students but perhaps suitable for young ophthalmic trainees of registrar status desirous of only a superficial insight into the subject. The diagrams are well done but there are not many.

The text has been kept up to date with references to such recent advances as Fresnal prisms and the correction of fixation disparity. In contrast, it is a pity that orbital injuries receive scant mention, and some schools of orthoptics might criticize the treatment advocated for abnormal retinal correspondence.

I. M. DUGUID

Lymphography—Clinical and Experimental

Edited Brendon W. M. Gooneratne, Ceylon. 250 × 190 mm. Pp. 194 + xii. Illustrated. 1974. London: The Butterworth Group. £12·25.

THIS book will be of great value to those studying filariasis and treating patients with Bancroft's filariasis. The chief editor, Dr Gooneratne, reports his lymphographic studies of the genesis of filarial infections in animals. Dr Cahill, Director of the Tropical Disease Center of New York, contributes an authoritative chapter on lymphography in Bancroft's filariasis. It includes a picture of the spectacular labyrinth of vessels seen in the cisternal region of patients with chyluria, from which emanate the incompetent lymphatics leading to the urinary tract and which may be so effectively ligated in the treatment of the disease. Unfortunately, the thoracic ductogram is badly reproduced and reversed left to right. It shows conditions which one now considers abnormal: the dye is still present 24 hours after injection and the duct is dilated and deformed. Such stagnation is undoubtedly a factor in the reflux of chyle.

The remainder of the book deals with techniques, applications, normal radiographic anatomy (which is distinct from classic textbook or cadaver anatomy), secondary and primary lymphoedemas and malignant disease.

Such a short work cannot cover so many large subjects thoroughly, but it remains a stimulating book and, despite imperfections, a source of intellectual pleasure and stimulus.

J. B. KINMONTH

Bronchial Carcinoma

Thomas W. Shields, Chicago, and Roy E. Ritts, Rochester, Minnesota. 225×150 mm. Pp. 181+ix, with 40 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. $12.75.

This book is in the nature of a long essay on bronchial carcinoma. Obviously the authors have much practical experience of the subject but as their work is cast as a review essay it partakes of the disadvantages that this often has. It tends to lack the authority and stimulation that one expects from a personal account, but at the same time it gains from presentation of a critical analysis of the relevant literature, although we note once more the usual habit in an American publication that the review literature is excessively American. The 15 pages of references contain only the equivalent of 2 pages that are not from the United States.

The presentation of the standard accounts of the condition is orthodox and sound. It contains a useful analysis of the indications and limitations of radiotherapy and chemotherapy and of the various attempts at a formal grading of types of bronchial carcinoma and their significance, and for this reason is a useful source of reference. Experience with this disease teaches one that prognosis and curability often depend on some obscure biological factor, and this is opened up by the accounts of immunity and immunotherapy by the second author, Professor Ritts. The introduction of this feature recognizes probably the most important future in the development and the nature of the cure of bronchial carcinoma. One notes certain omissions; thus on p. 115 the 5-year survival rates for pneumonectomy is given from the literature as mostly below 25 per cent with only 2 over 30 per cent, but no mention is made of an article published in 1964 in the English literature of a survival rate of 35 per cent, and the prognosis is not considered beyond 10 years. This is scarcely realistic. The radical types of operation are dismissed casually and with little or no analysis; particularly striking is the virtual dismissal of the great merits of intrapericardial resection.

BROCK

A Manual of Head Injuries in General Surgery

Graham Martin, Wellington, New Zealand. 195×125 mm. Pp. 158. Illustrated. 1974. London: William Heinemann. £2.

This book, according to its preface, is written mainly for 'the general surgeon who has to manage head injuries and the postgraduate student who must sound as though he can'.

The pathology of head trauma, management, the indications for surgical intervention and operative techniques are all presented in a clear concise fashion. It is assumed that the reader will be unlikely to have access to most of the ancillary methods of investigation used in neurosurgical centres and accordingly the use of inspection burr holes is strongly emphasized.

As in all textbooks, not every statement will meet with unqualified acceptance by every knowledgeable reader. The degree to which the administration of steroids influences traumatic brain oedema, for example, and the efficacy of inducing brain expansion by the intraventricular instillation of fluid in the treatment of chronic subdural haematoma are subjects about which unanimity of opinion is lacking in the neurosurgical world. In the present instance such matters, which are not of major importance, are rightly treated in a refreshingly dogmatic manner which in no way detracts from a presentation of head injury management which might well serve as an introduction to the subject for the neurosurgeon in training, while at the same time fulfilling admirably the author's purpose in writing this excellent book.

IAN MCCAUL

Symposium on Reconstructive Hand Surgery. Volume 9

Edited J. William Littler, New York, Lester M. Cramer, Philadelphia, and James W. Smith, New York. 280×220 mm. Pp. 324+x, with 458 illustrations. 1974. London: Henry Kimpton. £20·20.

This is Volume 9 in a series produced by the Educational Foundation of the American Society of Plastic and Reconstructive Surgeons and reports the proceedings of a meeting held in New York, 2–4 November 1972. It includes the deliberations of thirty-five contributors of whom all except three were from the United States. It therefore reflects American thinking and teaching on the subject.

It is a beautifully produced and well-edited book which deals with subjects often omitted or poorly presented in standard textbooks on hand surgery. The volume is divided into nine sections, providing thirty-six short chapters in all (each with a list of references). Each section ends with a report of discussions among those attending (a feature which enlivens the reading matter) which range widely from aetiology and pathogenesis to technical details.

One may question the need for yet another book on hand surgery, but the quality of this volume dissipates any doubts about its academic value. It is difficult to pick out any single chapter for praise when clearly the whole volume has been so carefully edited. Four chapters are devoted to microsurgery, a subject currently in vogue, yet there is a well-illustrated chapter on splints which are still cumbersome and ugly. How long can a tourniquet be left on? Wilgis explains what happens during ischaemia and how to avoid complications.

Indeed, there is something for everyone interested in or actually concerned with surgery of the hand. Despite its excellence the price may preclude many from the purchase, but those who do will have to be prepared to lend their copy and keep a written record of the borrower's name!

JAMES CALNAN

ARMOUR TEMPORARY BIOLOGICAL DRESSING CAN SOLVE THE IMMEDIATE PROBLEM OF TISSUE LOSS COVERAGE AND REPAIR

effective in the treatment of

- partial thickness burns
- debrided full thickness burns
- traumatic skin loss injuries
- soft tissue defects
- decubitus and vascular ulcers

The many advantages of using a biological dressing are

- dramatic reduction of pain
- reduction of fluid and protein loss
- reduction of heat and energy loss
- reduction of infection
- increase in mobility
- protection of exposed tendons, vessels and nerves
- promotion of healing
- psychological improvement of the patient
- improvement of scarring
- In full thickness burns, used as a "test material" to predict the readiness of the granulating bed to accept autograft. This results in a more economical use of autograft material.

Armour porcine skin dressings are presented in sterile lyophilised form, can be conveniently stored without refrigeration and may be reconstituted prior to use in sterile water or balanced electrolyte solution.

Package and size availability is as follows:
Boxes of 5 x 1 sq. ft. roll 3"x 48"
Boxes of 5 x ¼ sq. ft. roll 3"x 12"
Boxes of 10 Patches 2½"x 4"
Boxes of 5 x Wide Strip 8"x 18"
Boxes of 5 x Wide Half Strip 8"x 10"

Physical Examination of the Surgical Patient:

An Introduction to Clinical Surgery 4/e

By J. Engelbert Dunphy, M.D., Professor of Surgery, University of California School of Medicine, San Francisco, California, and Thomas W. Botsford, M.D., Associate Professor of Surgery, Harvard Medical School.

This fourth edition of **Physical Examination of the Surgical Patient** has undergone extensive revision, and introduces such new emphases as the problem orientated record and pathophysiologic mechanisms of surgical disease. Major changes to this edition appear in the elective examination of the breast, heart, abdomen, and the cancer patient; the emergency examination of the chest, abdomen, and the thermally injured patient. A more clear and concise listing of supplementary readings replaces the old bibliography, and many of the older figures have been replaced with new ones. A second colour plate of epidermal lesions has also been added.

The LOR-1A
APPARATUS

CHRONIC TONSILLITIS

successfully treated by ultrasonic therapy

Detailed information available from

V/O MEDEXPORT

31 Kakhovka, Moscow 113461, USSR. Telex 7247
Tel: 121-01-54

The LOR-1A apparatus produces mechanical vibrations of ultrasonic frequency which have a therapeutic effect on infected tonsils. Clinical tests have shown 75% success in patients treated. Advantages of the LOR-1A are its small dimensions and low weight (less than 5 kg) and its proven safety, reliability and ease of operation. Small ultrasonic generator of low operating voltage permits direct treatment to tonsils.

CHURCHILL LIVINGSTONE

FUNDAMENTAL TECHNIQUES OF PLASTIC SURGERY—and their surgical applications

IAN A. McGREGOR

1975 Sixth edition 328 pages Illustrated **£6·00**

This book describes the basic plastic surgical techniques, so often passed over by more advanced textbooks, but nonetheless fundamental, with full discussion of the relevance and use of these methods in related specialities. The entire book has been revised, with the chapter on flaps now divided into those with an 'axial pattern' and those with a 'random pattern' according to their vascular characteristics.

TRAUMATIC NERVE LESIONS OF THE UPPER LIMB

Monograph No. 2 of the Groupe d'Etude de la Main

Edited by J. MICHON and ERIK MOBERG

1975 124 pages Illustrated **£8·50**

This is the second of the G.E.M. monographs to appear in English. It deals with one of the most difficult areas in hand surgery, and one in which much international research is taking place. This volume reports the progress of such research and points the way to future developments.

SURGICAL DISORDERS OF THE PERIPHERAL NERVES

SIR HERBERT SEDDON

1975 Second edition 346 pages Illustrated **£12·00**

Although only three years have elapsed since the publication of the first edition, this book has needed revision. Electrodiagnostic investigation has boomed; what are now called entrapment neuropathies have been studied in great detail; the operating microscope has come into regular use; and the scope of autologous nerve grafting—which the author was the first to employ—has been greatly extended.

A new concept in surgical lighting
the DAYSTAR
major surgical light

Made in England by

DRAYTON CASTLE
SYBRON CORPORATION

Light Quality The **Daystar** provides cool shadow free colour corrected light giving maximum illumination and minimum heat in the surgical field.

An infinitely variable intensity controller means that you can regulate the level of light to suit your own requirements.

Positioning The **Daystar's** unrivalled ease of mobility puts the light where you want it and keeps it there without drift.

A snap-on autoclavable handle is provided to allow final surgical alignment where necessary.

Supplementary lights
An optional **Orbiter** attachment is available complete with its own intensity controller.

Track lights If you prefer track lighting the **Twinstar** combines **Daystar** quality light with twin track configuration.

stone stopping comments no.4

In a recent study[1] measurements of ^{47}calcium and of urinary calcium excretion were made in 125 cases of urolithiasis (78 solitary stone, 47 recurrent).

The authors found that 57 out of 60 patients with hypercalciuria showed raised absorption of ^{47}Ca, whereas 49 out of 106 patients showing similar hyperabsorption of calcium had *normal* calcium excretion. The authors concluded that "... a majority of stone formers, whether they are hypercalciuric or not, absorb calcium excessively from the intestine and this is more prevalent in cases of recurrent urolithiasis."

As a sequel to investigation 1, the same authors[2] studied the effect of Sodium Cellulose Phosphate on intestinal calcium uptake. In comparison to a low calcium, low oxalate diet; "Sodium Cellulose Phosphate can significantly diminish the absorption of calcium from the intestine; there is concomitant diminution of urinary calcium excretion. The plasma levels of the divalent cations do not appear to be influenced by this therapy."

Dosage in this study was varied to evaluate therapeutic effect. "Five grams reduced the intestinal calcium by as much as 85% and even a 1 g dose resulted in a 50% reduction ... Such a dose (5 g), however, is probably essential when it is considered that the substance will ordinarily be dispersed throughout a semi-solid food bolus." Optimum administration time was considered to be 5 g t.i.d. at meal times, or within 1 hour after food.

In terms of side-effects and toxicity, the authors stated "Serum levels of calcium and phosphorus were not altered in any of the patients even when the substance had been taken for a period as long as 7 years in a dose of 5 g 3 times daily." There was no diarrhoea or intestinal disturbance, and patients found SCP reasonably palatable and easy to take.

Presentation

Whitish cream powder packaged in paper aluminium polythene single-dose sachets of 5 g each. Supplied in packs of 100.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 61. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

PRESENTATION OF STATISTICS

Authors are reminded that with the frequent use of statistical analysis in biological writing of all kinds it is desirable that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinical trials the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached.

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

Disaster Planning

Proceedings of a Symposium held at the Royal Naval Hospital, Haslar, Gosport, Hants.

Edited by Surgeon Commander J. W. RICHARDSON, OBE, FRCS, RN,
Consultant Surgeon, RN Hospital, Haslar.

These papers, which have been presented by those people recognized as experts in their particular field, discuss many contentious points which underline the need for an agreed policy regarding the management of casualties arising from disaster situations. This book is a 'must' for all those concerned with the formulation of disaster plans: police, fire service, ambulance, doctors (accident surgeons, pathologists), hospital staff, voluntary service, coroners, the media. Those concerned with running nuclear power, industry, the railways, aircraft and ships and the sea.

144 pages   19 illustrations   paper covers   £5·00 net.

Chest Injuries

G. KEEN, MS, FRCS, *Thoracic and Cardiac Surgeon, United Bristol Hospitals and Frenchay Group of Hospitals, Clinical Lecturer in Thoracic Surgery, University of Bristol.*

There are many pitfalls of diagnosis and treatment in chest injury that are responsible for avoidable complications and deaths. The book is based on the author's own experience. It will be useful to general surgeons, accident surgeons and anaesthetists and it will also be a practical guide for those who find themselves dealing with a case that is outside their experience.

192 pages   78 illustrations   paper covers   £7·00 net.

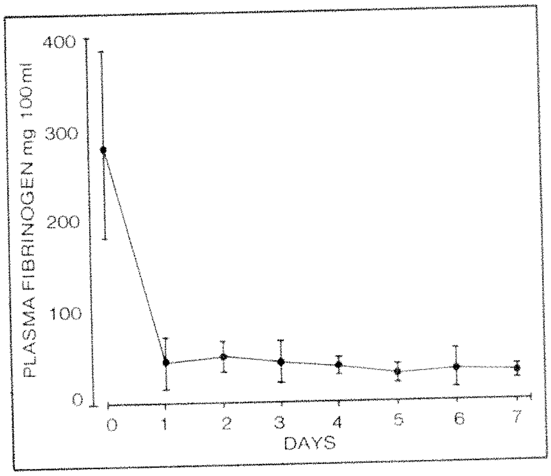
A new concept in the control of occlusive vascular disease.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR. (1971). Thromb Diath Haemorrh, 45, 43.

Its name is Arvin.

This unique drug is now available to specialists, for routine anticoagulant therapy, and to researchers into thromboembolic disorders.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

The consistent does-effect relationship of Arvin allows simple and precise methods of control.

On this basis, we recommend Arvin wherever controlled therapeutic defibrination is desirable.

Full prescribing information, and clinical evidence from studies on the broad range of thromboembolic disorders, are available on request.

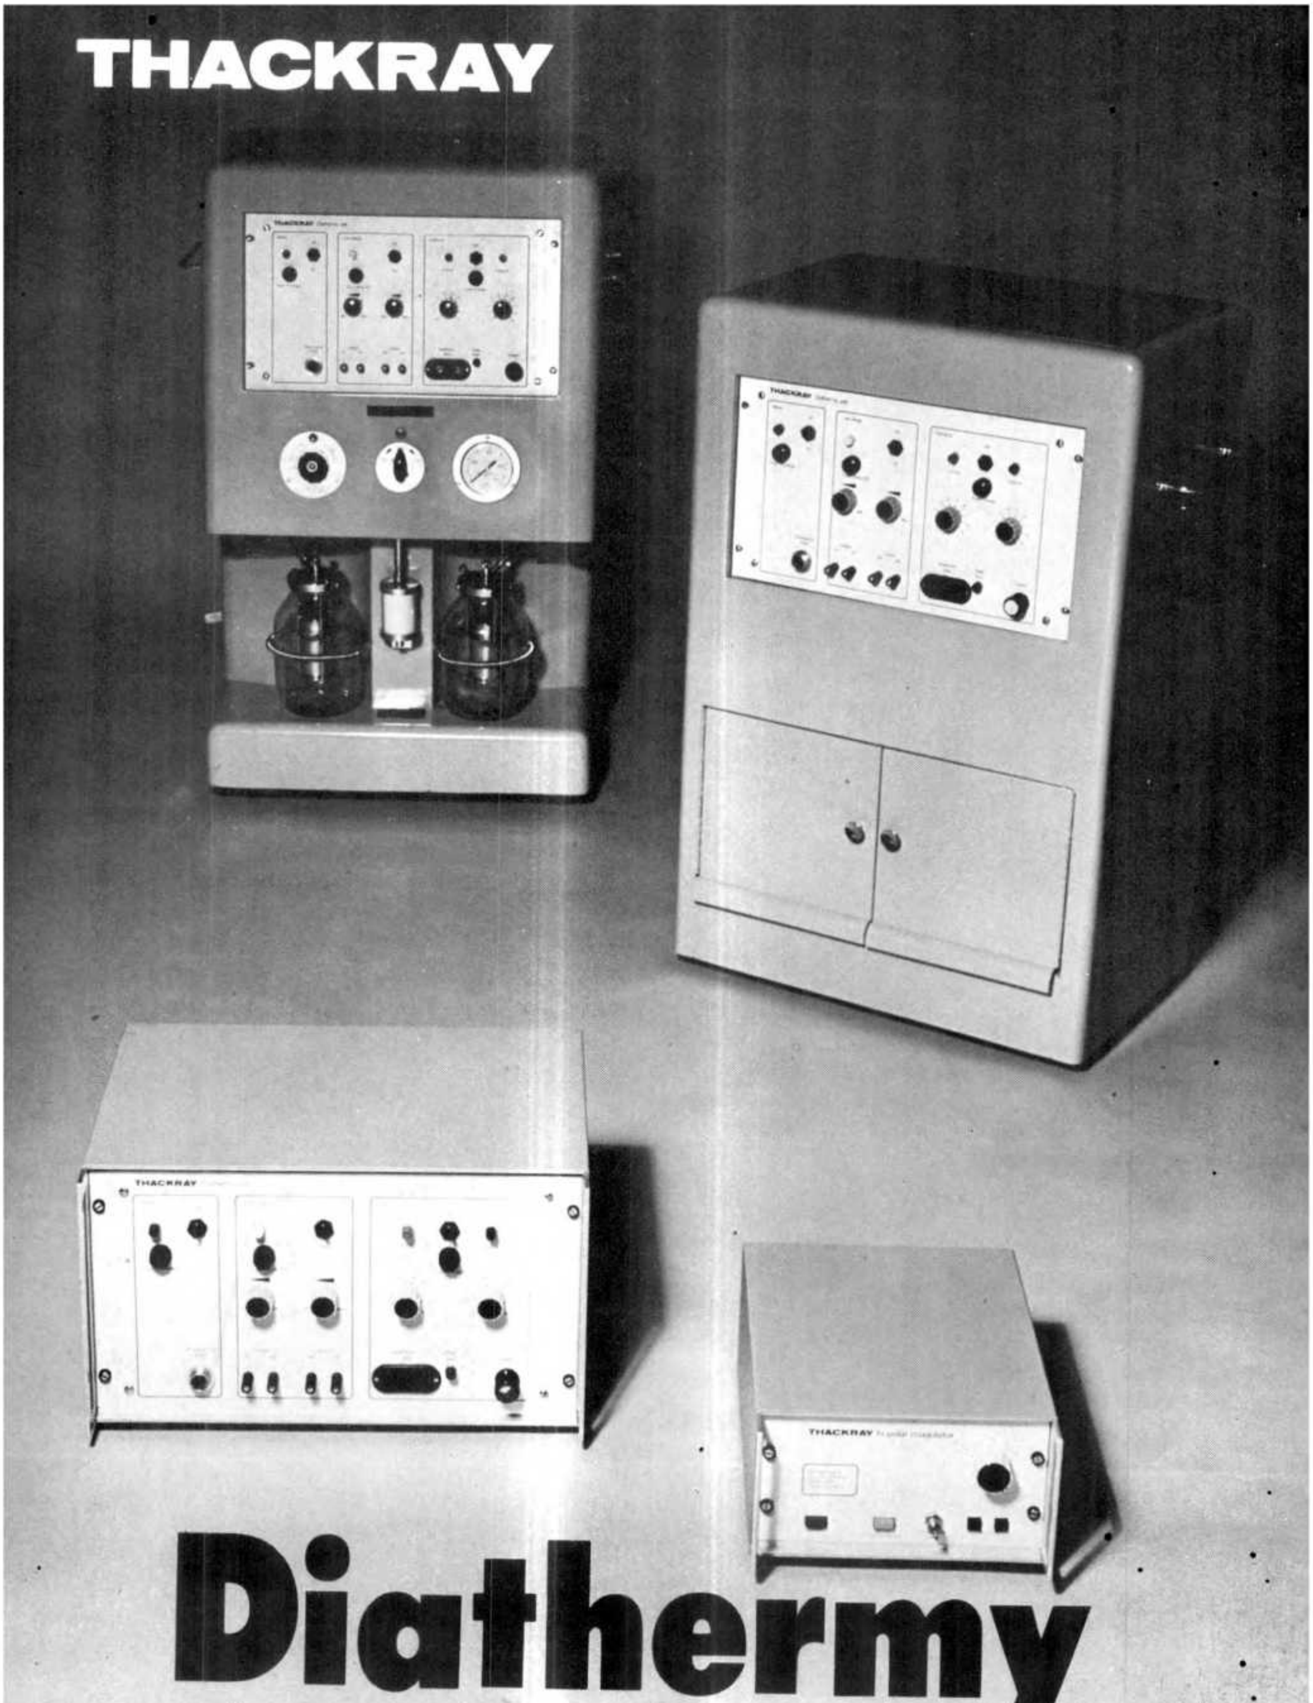
THACKRAY



Diathermy

Thackray Electro-Medical products for the '70's incorporate the latest features in engineering and design, manufactured to a high standard by our technicians, renowned for quality throughout the surgical world. Each of the products illustrated fulfils particular requirements essential to the surgeon. Every item comprises high quality components, being thoroughly and comprehensively tested before leaving our factory.

The LOR-1A APPARATUS

CHRONIC TONSILLITIS

successfully treated by ultrasonic therapy

The LOR-1A apparatus produces mechanical vibrations of ultrasonic frequency which have a therapeutic effect on infected tonsils. Clinical tests have shown 75% success in patients treated. Advantages of the LOR-1A are its small dimensions and low weight (less than 5 kg) and its proven safety, reliability and ease of operation. Small ultrasonic generator of low operating voltage permits direct treatment to tonsils.

Observations on peripheral and central temperatures with particular reference to the occurrence of vasoconstriction

LORD BROCK, J. M. SKINNER AND J. T. MANDERS*

SUMMARY

The importance is emphasized of the inadequacy of the term 'body temperature', but that both core temperature and the peripheral temperature must be considered. The assessment of vasoconstriction is informative, and advantage should be taken of the exact information that can be provided by an electro-thermometer as opposed, for example, to a touch of the hand. The core temperature is taken from the rectum, the nasopharynx or tympanic membrane, and the peripheral temperature from the great toe.

If the peripheral temperature falls the loss of body heat is prevented and the core temperature rises. If this is not understood or not recognized misguided attempts may be made to try to reduce the raised central temperature by cooling the skin. This can result in a further rise of central temperature. The recognition of peripheral vasoconstriction enables a proper assessment to be made of its basic cause and of the necessary treatment.

The most important cause is hypovolaemia from blood loss and a detailed account is given of how this should be recognized, especially by a study of the gradient between central and peripheral temperatures. Such studies should be a routine in any severe illness, whether medical or surgical, in which circulatory deterioration is likely, especially after major operations or injuries.

Study of the temperature of the heel (hindfoot) as well as of the toe (forefoot) can indicate a selective 'shutdown' of peripheral circulation that reveals an especially critical circulatory state.

THE results are presented of studies on the effects on body temperature of environmental and of internal factors, especially in relation to differences between the peripheral and the central or core temperature. The subject is large and complex and turns chiefly on the development, causation and significance of peripheral vasoconstriction. Much can be learned from a study of vasoconstriction, and the peripheral temperature has been used as a means of measuring this important mechanism. It should no longer be thought sufficient to judge what is happening to the skin temperature by a simple touch of the hand. Sensitive electro-thermometers enable the measurement, with considerable accuracy, speed and advantage, of fluctuations in this valuable and important parameter. Such methods have hitherto been largely neglected. The temperature of the skin is essentially an indication of the resultant between the degree of patency (constriction versus vasodilatation) of its vessels and of the flow and pressure of the circulation to it. Vasoconstriction of skin vessels can be via an axon reflex or as part of general sympathetic activity.

It is necessary to emphasize that it is not enough to speak of 'body temperature', but that both the core temperature and the peripheral temperature must be considered. The core temperature can be measured from the rectum, from the nasopharynx, from the lower one-third of the oesophagus or from the tympanic membrane, although each site may have disadvantages or slight differences. The peripheral temperature is measured from the ball or the side of the big toe but valuable information can also be obtained by measuring the temperature of the hindfoot (heel). If there is general body cooling the temperature at each of these sites, central and peripheral, will fall together (*Fig.* 1). Under anaesthesia the thermoregulatory mechanism becomes paralysed and the subject behaves poikilothermically. In the intact homeotherm when the core temperature falls beyond the tolerance of the 'thermostat', peripheral vasoconstriction occurs to limit heat loss from the body and this persists until the core temperature is restored. As the peripheral temperature falls the central temperature may rise (*Figs.* 2, 3). This is due to peripheral vasoconstriction limiting the loss of body heat and thus the core temperature rises as a result of the continuance of body metabolism. The rise may be

---

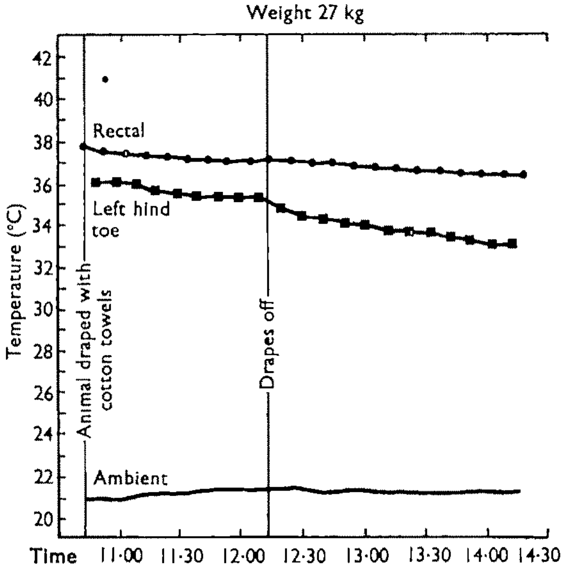

Fig. 1. With general body cooling the central and peripheral temperatures fall together.

even greater if shivering occurs and may reach an important degree of hyperpyrexia (e.g. 40 °C or even higher).

If the rise in body temperature is general (as in a febrile illness) and is accompanied by the hot, flushed skin of vasodilatation, then the practice of trying to reduce the high temperature by some form of surface cooling, such as tepid sponging, is acceptable. However, if the presence and the significance of a cool or cold skin due to vasoconstriction is not appreciated and that the rise in central temperature is due to it, the high central temperature may be allowed to dominate the clinical picture and misguided attempts may be made to try to reduce it. These attempts will consist essentially of applying cold in some form to the skin, such as tepid or cold sponging or by directing a stream of cold air over the body from a fan or simply by exposure to a draught such as from an open window, or the thermostat of an air-conditioned room may be turned down several degrees. Applying cold to the skin fails to extract heat and indeed increases the constriction of the skin vessels. *Fig.* 3 shows how the attempt to reduce 'body temperature' in this way not only fails but results in it rising even higher. This is,

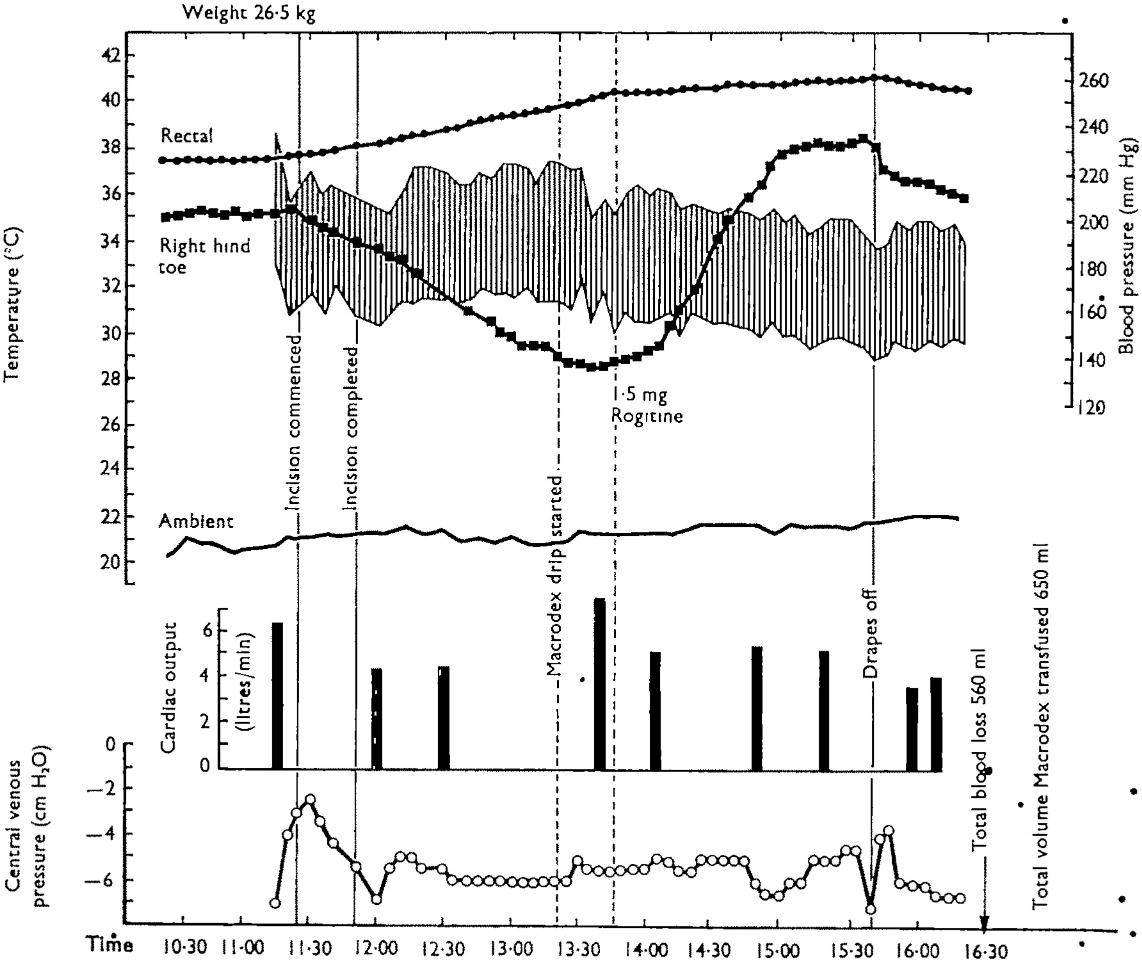

Fig. 2. With a fall in surface temperature from peripheral vasoconstriction due to blood loss the central temperature rises, in this case to over 40 °C. Correction is seen to occur when blood loss is replaced and vasodilatation is encouraged (by Rogitine).

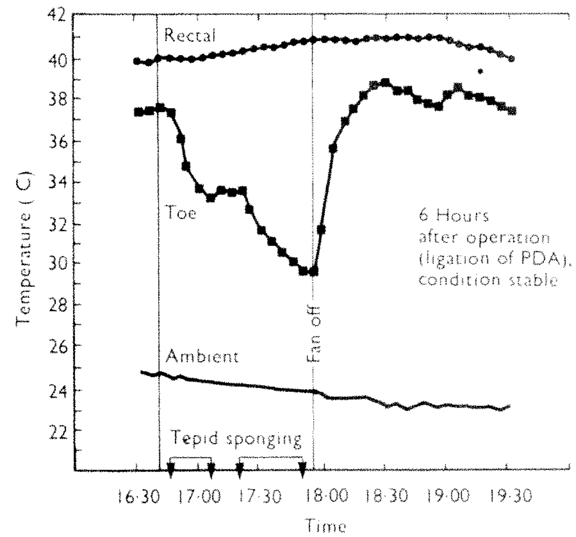

Fig. 3. The misuse of tepid sponging and a fan in an empirical attempt to reduce a raised central temperature of 40 °C. The skin temperature fell to below 30 °C. The skin temperature rose and the central temperature fell when the tepid sponging and the fan were stopped. PDA, Persistent ductus arteriosus.

in fact, a demonstration that tepid sponging and similar methods not only fail when the true situation is not recognized but actually aggravate the condition. The only logical measure is to produce peripheral vasodilatation which will permit increase of heat loss from the skin and hence lowering of the core temperature (*Fig.* 4). In other words, both doctors and nurses should be taught that in the absence of a warm flushed skin it is wrong to try to reduce temperature by some empirical method. Not only is it wrong treatment but the clinician reveals that he has failed to grasp the significance of the cold skin that should point the way to some cause other than 'fever' for the raised central temperature. He has missed the chance of elucidating what is really wrong with the patient.

There are a number of causes for peripheral vasoconstriction and the cold skin that results. When in an equable environment peripheral vasoconstriction is exhibited by a low peripheral temperature and the 'core' temperature is raised above normal, then it is likely that the peripheral vasoconstriction is due to a non-thermoregulatory cause. The very important one to consider is hypovolaemia from any cause, but especially from blood loss. This provides the primary cause for a vasoconstriction which is due to a fall in cardiac output as a result of diminished venous return and hence stimulation of the aortic mechanoreceptors that initiate peripheral vasoconstriction. It is necessary to sound a note of warning, for if this vasoconstriction is treated solely by the exhibition of vasodilators the result can be disastrous and even fatal because a sharp fall in systemic blood pressure results from an increase in the arteriolar and capillary bed (*Fig.* 5). The hypovolaemia must first be corrected by transfusion and only then is it safe to establish vasodilatation. Examples of this have been given in earlier articles (Spitzer and Brock, 1968; Ross et al., 1969, *Fig.* 6) and an example is given in *Fig.* 7. If the cause of an important gradient between the central and peripheral temperatures is hypovolaemia, additional information will be provided by measurement of the central venous pressure (which will be low), a low urinary output and perhaps a low arterial pressure and raised pulse rate (*Figs.* 5, 6). However, it should be noted that peripheral vasoconstriction assessed by temperature records is a more sensitive indicator of hypovolaemia and can provide evidence

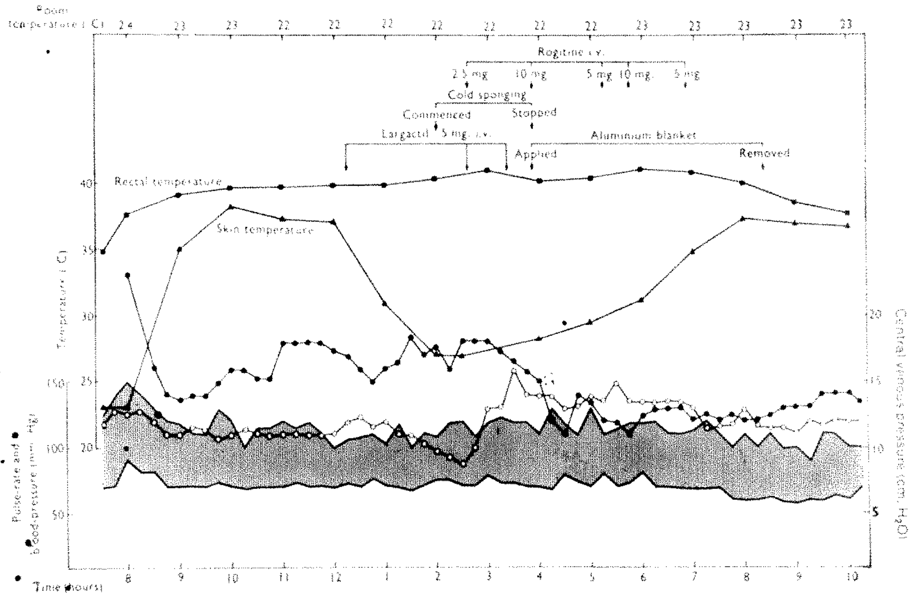

Fig. 4. Central heat retention. Treated empirically by cold sponging which aggravated the peripheral vasoconstriction and the rise in rectal temperature. The response to administration of an α-adrenergic blocker (Rogitine) is well shown and was fully satisfactory.

of this even when blood pressure and central venous pressure remain within normal limits. If the cause of the hypovolaemia is blood loss this can also be reflected in the haematocrit and the haemoglobin levels. It is lamentable, even pathetic, that in spite of such rich clinical changes which should tell their tale, misguided attempts should be embarked upon to reduce a raised central temperature by empirical methods that ignore a scientific assessment of the true situation. In such a case the information given by a study of the gradient between the central and the peripheral temperatures is informative, is more sensitive and should always be used.

There are other causes of hypovolaemia than haemorrhage, as for instance in various dehydrating conditions. Temperature studies can be of great value in any severe illness, medical or surgical, in which circulatory deterioration is likely to occur, or is actually occurring. An example of this is phaeochromocytoma (Brock, 1975) in which severe hypovolaemia may be present, is made worse when operation is done and may be wrongly treated by the use of vasoconstrictors (such as noradrenaline) in a misguided attempt to support the failing circulation when what is needed is transfusion to correct the hypovolaemia.

Hypovolaemia may be aggravated by the pooling of blood within vessels apart from actual haemorrhage. This is why important hypovolaemia is an accompaniment of certain major operations and a plea is

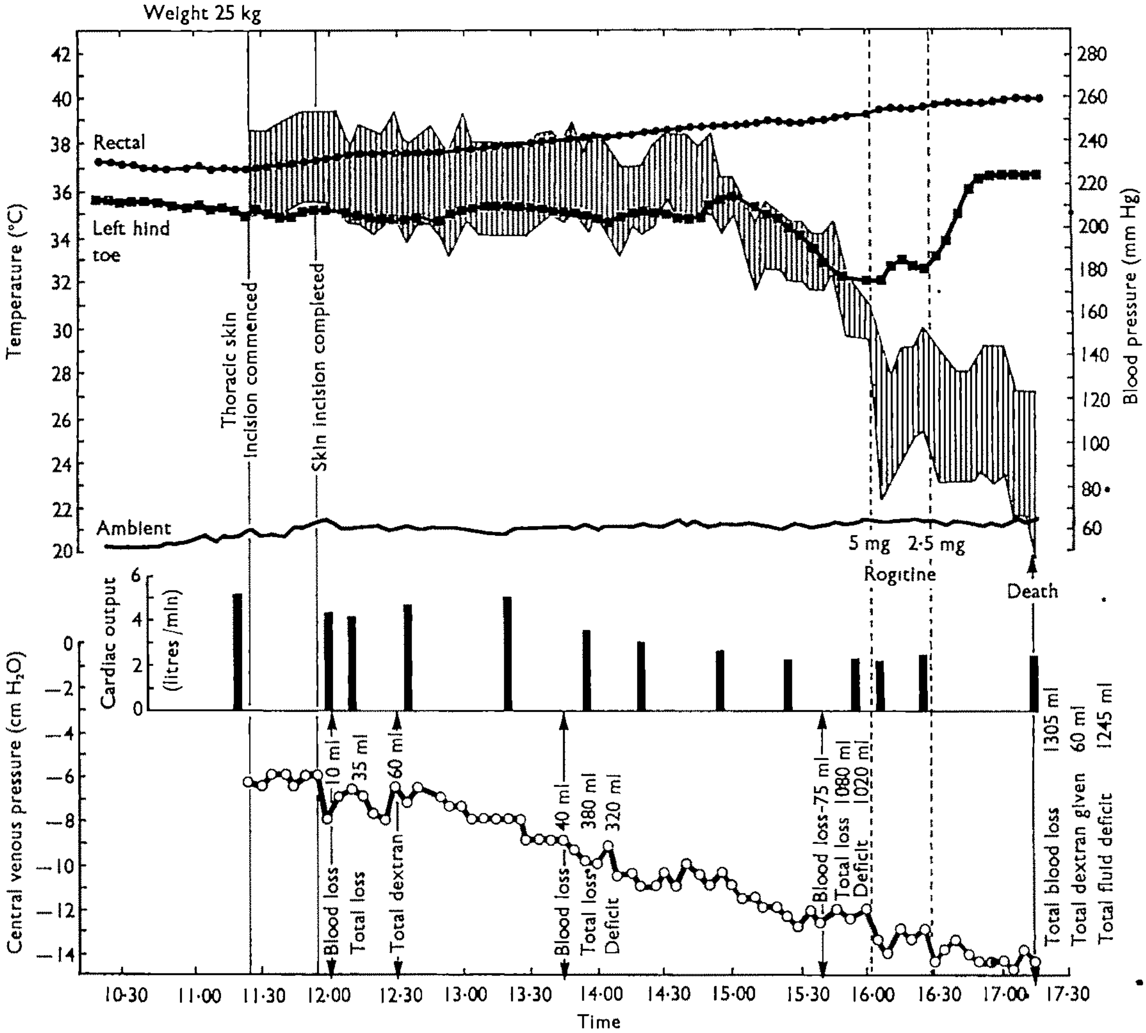

Fig. 5. The effect of blood loss (1080 ml) and inadequate replacement by only 60 ml. Estimated blood volume = 2350 ml. By 16.00 hours the toe temperature had fallen to 33 °C and the rectal temperature rose to 39·5 °C. The blood pressure had fallen from 240/200 to 160/140 mm Hg and the central venous pressure had fallen from −6 to −12 cm H_2O. At 16.00 and 16.30 hours two doses of Rogitine, 5 and 2·5 mg, were given, resulting in a rise in the toe temperature to 37 °C and a levelling off of the rectal temperature. This was accompanied by a sharp fall in blood pressure to 130/70 mm Hg and a fall in central venous pressure to −14 cm H_2O. The total blood loss by 17.30 hours had reached 1305 ml, a deficiency of 1245 ml (nearly 50 per cent of blood volume). At this time the blood pressure fell right away and death occurred suddenly. This demonstrates well the lethal effect of causing peripheral vasodilatation in the absence of replacement of blood loss.

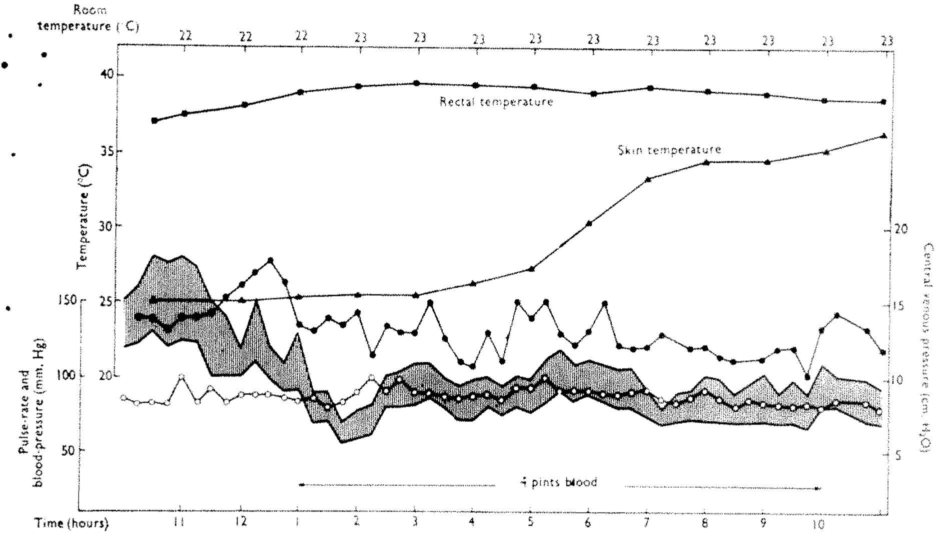

Fig. 6. Severe hypovolaemia and prolonged vasoconstriction following aortic valve excision and replacement. Note the concomitant fall in blood pressure and the low venous pressure. It was necessary to give 2·4 litres of blood before a stable thermal state was achieved. Blood replacement should have been begun earlier and more massively and should have been accompanied by a vasodilator drug (chlorpromazine). (Ross et al., 1969.)

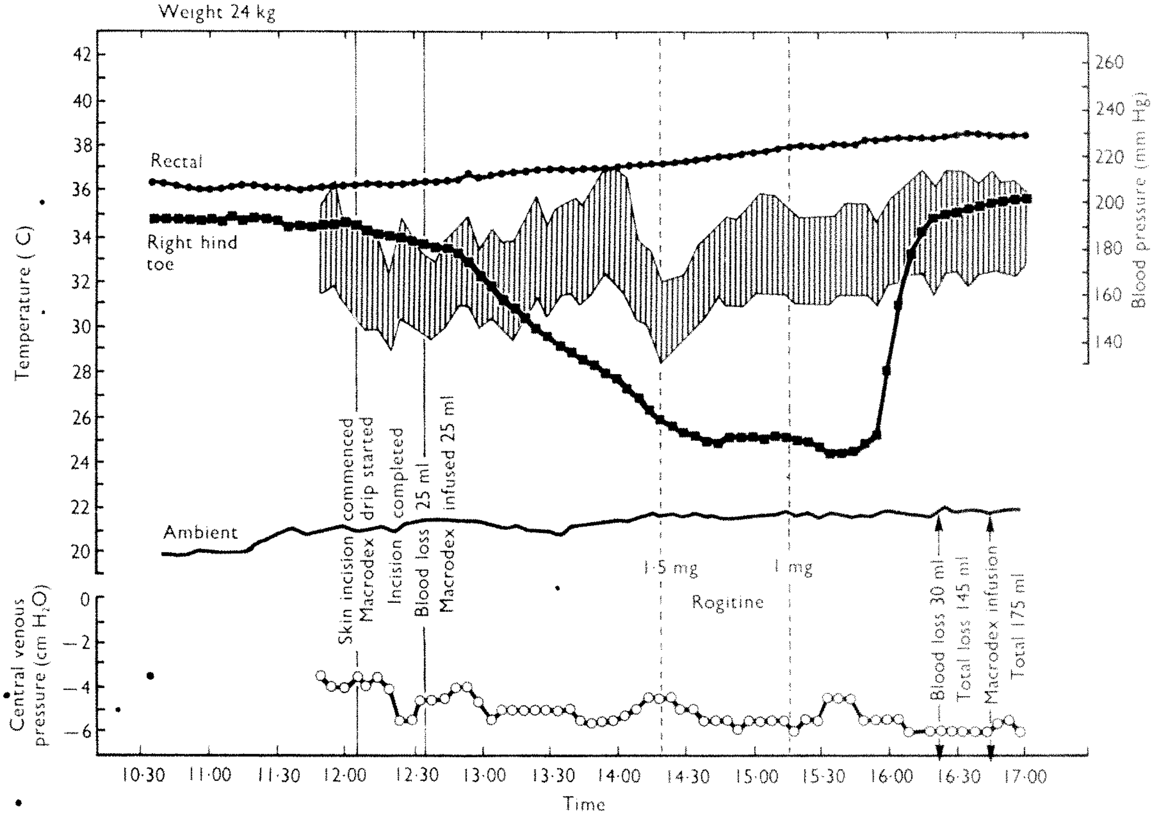

Fig. 7. The effect of an incision and blood loss in causing severe peripheral vasoconstriction (toe temperature 25 °C) and a rise in central temperature to 38 °C (gradient 13 °C), uncorrected by replacing the measured blood loss but completely corrected by Rogitine. The toe temperature rose to 35·5 °C and the central temperature flattened out at 38·5 °C (gradient reduced to 3 °C). This was supported by Macrodex infusion of 175 ml to correct the total blood loss of 145 ml. Contrast with *Fig.* 5 in which no infusion was given to support the vasodilatation caused by Rogitine.

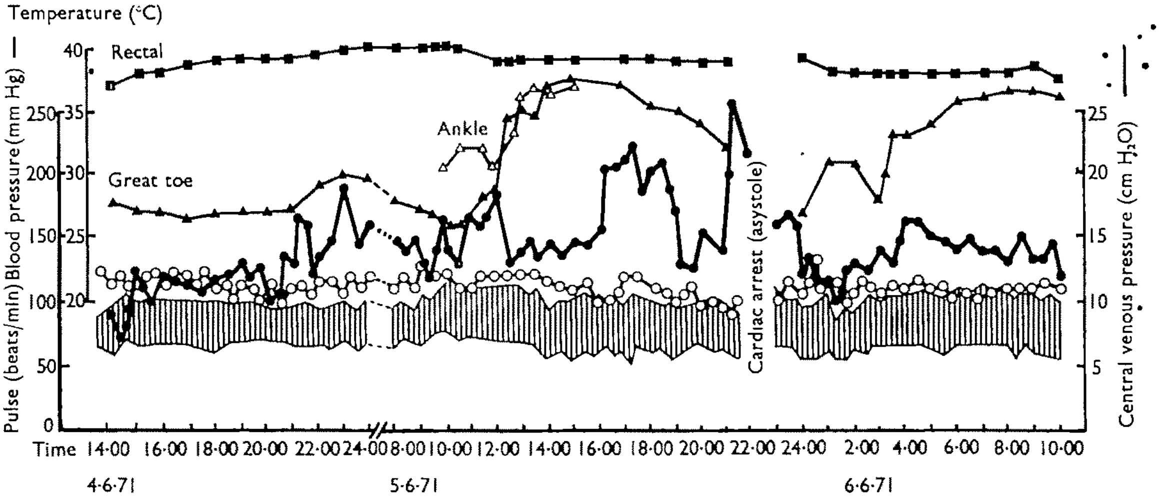

Fig. 8. The postoperative course following mitral valve excision and replacement. Initially there was a substantial gradient of 13 °C between the rectal temperature (40 °C) and the toe temperature (27 °C). The patient was not hypovolaemic as careful blood loss and replacement had been observed. On the morning after operation it was noticed that although the toes and forefoot were cold the heel and calf were warm. The heel or ankle temperature was then recorded and found to be 32 °C. As soon as the patient was extubated the toes became warm, the toe and heel temperatures both rose to 36 °C and the rectal temperature fell to 39 °C. This illustrates that selective peripheral vasoconstriction can occur and indicates an inadequate circulation. Subsequently, ventricular fibrillation occurred but responded to treatment. *See* text for further details.

made for the detection of this by using temperature studies. It is especially liable to occur after open heart operations, when in addition to frank blood loss there may be gross mal-distribution of fluid within the various body compartments. The success or failure of such critical operations may depend greatly on awareness of and detection of signs of significant hypovolaemia. Matthews et al. (1974a, b) have written of this and Matthews has also coined the phrase 'cold feet in cardiac surgery' that is based on the vasoconstriction that results and study of which can be such a valuable indication of what is happening in the critical state present. Matthews et al. proposed a simple nomogram based on the 'warm-up' time in 81 'normals' showing a consistent warm-up pattern which is independent of potential variables and that can be used in postoperative treatment. They claimed that this has become an indispensable part of routine postoperative care in their unit and they regarded it as the simplest and most effective available method of monitoring the circulation. From our own observations and experience over many years we agree with these conclusions.

It is also possible to show that there can be a selective control of peripheral temperatures if, in addition to the temperature of the forefoot as shown by the big toe, the temperature of the hindfoot is observed from the inner side of the heel or ankle. The potential significance of this is best illustrated by observations on a specific case.

Case report

Mrs R. A., aged 36 years, had an excision and replacement of the mitral valve because of severe regurgitation. As can be seen from *Fig.* 8, there was a substantial gradient between her central temperature (40 °C) and her toe temperature (27 °C). She was not hypovolaemic, careful fluid and blood replacement having been observed. On the morning after operation it was noticed that although the toes and forefoot were cold the heel and calf were warm. At 10 a.m., therefore, the heel or ankle temperature was recorded as well as that of the toe or forefoot and was found to be 32 °C. There was no anatomical cause for the cool forefoot and its poorer circulation, although the pedal pulses were small. As soon as the patient was extubated both the toe and heel temperatures rose sharply to 36 °C and the rectal temperature fell to 39 °C, as can be seen from the chart at noon (*Fig.* 8). The change in the forefoot and toes was striking; they were now warm and flushed and the pedal pulses were full and bounding. This change confirmed that the earlier discrepancy in the peripheral circulation was due to more severe distal vasoconstriction, a selectivity resulting from a deficient cardiac output that made it necessary for the body to shut down some of the peripheral circulation. In other words, a study of the toe, heel and rectal temperatures pointed to the precarious state of the circulation. Throughout the afternoon the improved peripheral circulation was reflected in the temperatures that continued at 37 and 35 °C, a normal gradient. During the early evening, as *Fig.* 8 shows, the toe temperature began to fall, the central venous pressure rose to 35 cm and the urinary output fell. Tamponade was suspected but there was a good response to Lasix and the central venous pressure fell to 21 cm. The toe temperature, however, fell to 32 °C and there was clear evidence of cardiac distress. This was confirmed when at 10 p.m. ventricular fibrillation and cardiac arrest occurred. Fortunately this responded to resuscitation. The gradient between the central and peripheral temperatures was still present but it lessened as her general condition improved and by early morning it had disappeared. Her circulatory state appeared stable, the toes were hot and the pedal pulses bounding and she made a good recovery.

This event led to us making a routine assessment of the heel as well as of the toe temperature because we felt that this enabled a more delicate assessment to be made of degrees of deficiency of the peripheral circulation. In fact, it could demonstrate a peripheral shutdown that indicated the inability of the body to maintain a full circulation. Soon after this another similar case presented, that of a young woman aged

24, also with severe and long-standing mitral regurgitation for which valve excision and replacement were necessary. In this case, however, the deficient toe and forefoot circulation, as demonstrated by the lower temperature in contrast to the ankle and calf temperatures which were warm and satisfactory, did not improve, indicating that the circulation was not capable of improvement, and death followed. Other similar instances have been observed and it has become clear that richer and more significant information about the circulatory state can be obtained from study of selective regions of the peripheral circulation. It can, of course, be tedious to take the temperature at many sites and little extra information may be obtained. Some people have in fact advocated study of the great toe temperature alone as a measure of a shock-like state (Matthews et al., 1974a, b). We feel that this can be incomplete, and in any event in managing a severely ill patient, especially after cardiac surgery, the extra information to be obtained for instance from the heel is invaluable. It has been stated that the temperature of the medial aspect of the thigh gives the average skin temperature (Teichner, 1958), and that this measurement on its own is sufficient. We cannot agree with this because it does *not* estimate peripheral vasoconstriction. This cannot be assessed by an average reading from a more central site.

Although great care may have been taken to measure and to replace blood loss, it is often found after a severe operation that the circulatory state does not improve until an additional 1, 1½ or even 2 litres of blood have been given as well as the measured blood loss (*Fig.* 6). Presumably this is because of pooling of blood in certain areas that causes a loss of effective circulating blood volume. It is in such cases that study of central and peripheral temperatures is particularly valuable and informative.

At the same time we must realize that although 'blood loss' in the widest sense may be the chief cause of a circulatory deficiency and of peripheral vasoconstriction, it is clearly important to study and to comprehend other causes of peripheral vasoconstriction if reliance is to be placed upon the temperature findings which they determine. In other words, what factors may be responsible for peripheral vasoconstriction and thus for a fall in toe temperature? This will be the subject of further communication.

Acknowledgements

This work was carried out with the help of a grant from the Department of Health and Social Security to which acknowledgement is due. We wish also to thank Mrs Christine Mills and Miss Catherine Richardson for valuable technical assistance.

Aorto-iliac reconstruction with special reference to the extraperitoneal approach

RAYMOND HELSBY AND A. R. MOOSSA*

SUMMARY

We have used the extraperitoneal approach for aorto-iliac reconstruction for lower limb ischaemia in over 130 patients. The operative exposure is excellent. Operating time is shortened and the upset to the patient much less than in the transperitoneal approach. We now believe that the method is suitable for use in the majority of aorto-iliac reconstructions. Patency rate 4 years after surgery for claudication is 89 per cent.

THE satisfactory results of aorto-iliac reconstruction are well documented in communications from many centres in different countries and stem from the pioneer work of Dos Santos, Rob and Eastcott, de Bakey, Cannon and Linton, to name but a few. Taylor (1973) has provided a valuable and realistic review of the scope and limitations of reconstructive arterial surgery and his comments and observations accord with our own experience. It is well recognized that in patients with a combination of femoropopliteal and aorto-iliac occlusive disease an aorto-iliac reconstruction will frequently increase the flow to and through the profunda femoris artery sufficiently to improve claudication or to save the limb from major amputation. When the disease is mainly confined to the aorto-iliac region, one can offer the patient a very high prospect of complete and lasting relief.

It would seem to the authors that no useful purpose can be served in reporting the detailed follow-up of further patients who have undergone aortic reconstructive operations unless the results are significantly better (or worse) than those in other series. This communication adds little to the existing store of information on postoperative results but seeks to influence surgeons to modify their technique.

As the proportion of our population over the age of 65 increases and since atherosclerosis is such a common disease, it is likely that the number of patients presenting for reconstructive surgery will continue to increase. The size of the load must inevitably mean that, as with urology, much of the work will need to be done by the general surgeon. Inevitably, the number of successful reconstructive operations will be approximately balanced by the need for major amputation in other patients, and it is the authors' belief that the same surgeon should accept equal responsibility for both groups. The purpose of this report is to emphasize that aorto-iliac reconstructions can be adequately performed by general surgeons trained in vascular surgery, and to underline the advantages and the ease of the extraperitoneal approach. This approach is by no means new. Rob wrote of it in 1963 and recalled that Astley Cooper had described it in *Guy's Hospital Reports* in 1836. It was recommended by Stipa and Shaw (1968), Douglas (1973) and Martin and Marston (1973); nevertheless we believe that it is still not widely used by surgeons doing vascular work. We have found the exposure quick and convenient, the general upset to the patient far less marked than in the transperitoneal approach and the incidence of postoperative distension, wound dehiscence, incisional hernia and chest complications negligible. Obesity is not a contraindication but rather an indication for the use of this approach. For these reasons the extraperitoneal exposure has become our method of choice and is now used in the majority of aorto-iliac reconstructions. Preoperative assessment does not differ from that used elsewhere, except perhaps that preoperative arteriography has not always been done. In particular, if a patient presents with severe rest pain or gangrene and has an absent femoral pulse on the affected side, when the contralateral femoral pulse is present, operation might well be undertaken without a preoperative angiogram.

In the years 1961–74, 330 aorto-iliac reconstructions were performed for lower limb ischaemia. During the same period 250 femoropopliteal reconstructions, over 500 lumbar sympathectomies and 375 leg amputations were done. In addition, about 800 nonvascular operations including routine urological and gastro-enterological procedures were performed each year on an undergraduate teaching unit consisting of 2 consultants, 1 senior registrar, 1 junior trainee registrar and 1 house surgeon at the Liverpool Royal Infirmary. About 90 per cent of the arterial operations were done by one surgeon.

Three basic operations—aorto-iliac disobliteration, aortofemoral bypass and, less frequently, iliofemoral bypass—were used. If the external iliac arteries were grossly diseased the problem was usually managed by an aortofemoral bypass graft rather than by disobliteration. The graft material used has been in nearly every case woven Dacron. Knitted velour Dacron has been used for iliofemoral grafts, but it is not yet available as a bifurcation. The anastomosis of graft to aorta has been either end to end or end to side—approximately an equal number of each. Prophylactic broad spectrum antibiotics (usually ampicillin) have been used routinely, being started a

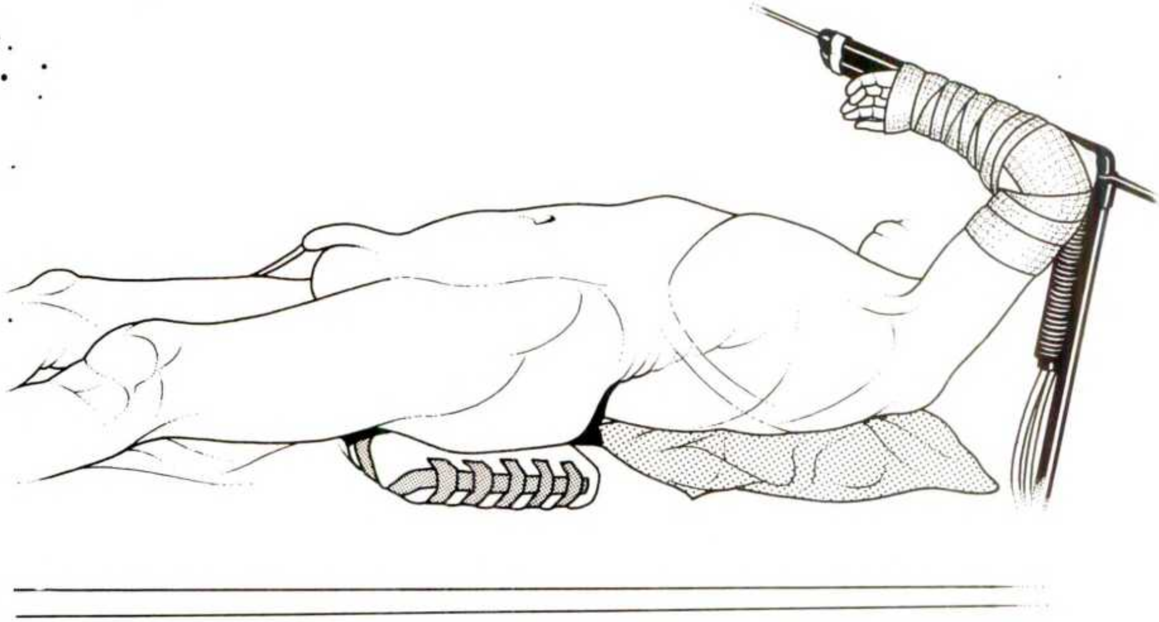

Fig. 1. Position of patient for extraperitoneal exposure.

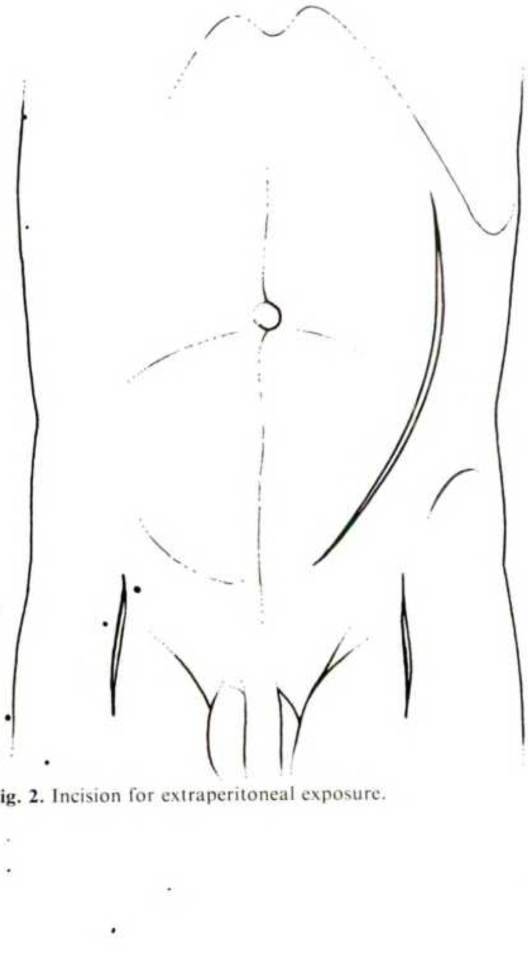

Fig. 2. Incision for extraperitoneal exposure.

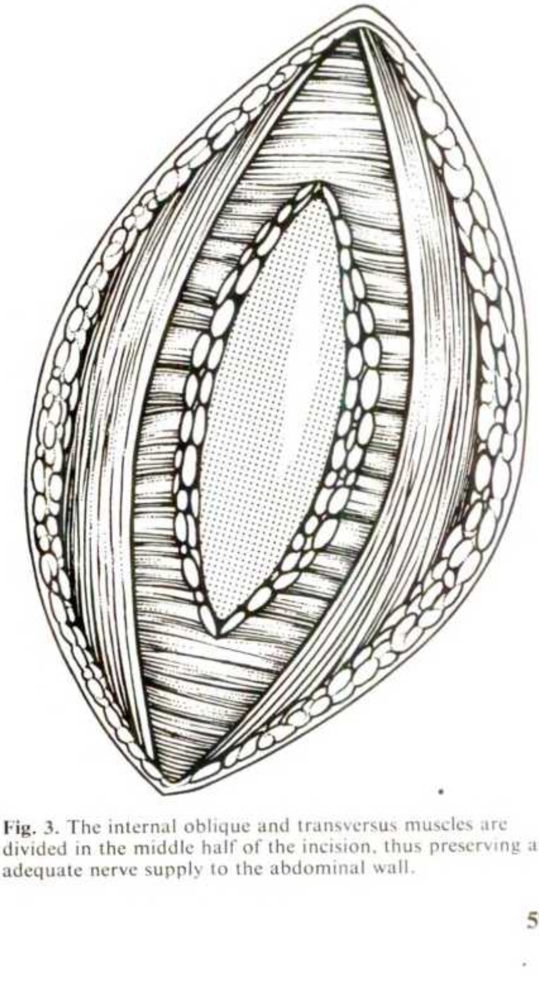

Fig. 3. The internal oblique and transversus muscles are divided in the middle half of the incision, thus preserving an adequate nerve supply to the abdominal wall.

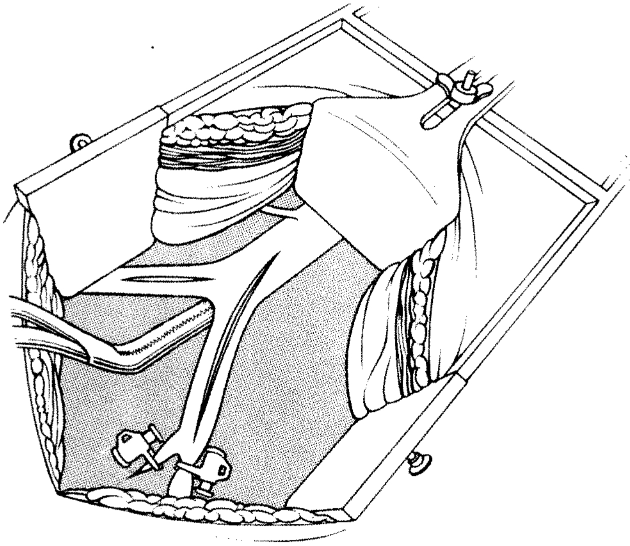

Fig. 4. Exposure of lower abdominal aorta and common iliac arteries.

few hours preoperatively and continued for 4 days. Originally heparin was given intraoperatively, but for the past 2 years a single loading dose of 10 000 units is injected intravenously before the induction of anaesthesia. Since the introduction of this latter method there has been no clinical evidence of pulmonary embolism, and indeed no clinical evidence of major deep venous thrombosis in the lower limb following aorto-iliac reconstruction.

For the extraperitoneal exposure certain points need emphasis. The left side of the patient must be tilted slightly upwards on sandbags and the ipsilateral arm supported (*Fig*. 1). Our incision differs somewhat from that described by Rob (1963) and resembles that of Rutherford Morrison. The skin incision is sickle-shaped with the upper end curving medially to the costal margin (*Fig*. 2). The external oblique muscle and aponeurosis is split along the line of its fibres. The underlying internal oblique and transversus muscles are then divided with diathermy in the middle half of the incision. The fibres in the upper and lower quarters of the incision are not divided, and this seems to preserve an adequate nerve supply to the abdominal wall (*Fig*. 3). The rectus muscle is not divided. The use of a Goligher self-retaining retractor is absolutely essential and overcomes the problem of retraction to which Rob (1963) refers in his paper. The instrument has been modified by us to provide different depths of blade, and it is no exaggeration to say that it saves one assistant—an important factor in many hospitals where skilled assistance is not always readily available. Abdominal packs are not required, only a small dab, with radio-opaque strip, being placed behind each blade of the retractor (*Fig*. 4). The abdominal incision is closed with a split tube drain. Redivac drains are used for groin incisions. It is quite possible through this incision to obtain an adequate exposure for disobliteration of the abdominal aorta and both common iliac arteries or, alternatively, for transection of the aorta, proximal disobliteration and end-to-end attachment of a bifurcation graft. Small aneurysms have also been resected through this approach. The distal graft anastomosis is performed in the groin, end to side, to the common femoral artery opposite the origin of the profunda femoris artery. When a bypass graft is inserted local common femoral disobliteration is often performed, and occasionally some type of profundaplasty. Left lumbar sympathectomy was performed concomitantly in the majority of operations by coagulation of the lower lumbar ganglia with diathermy. Postoperatively each patient received 500 ml of low molecular weight dextran (Rheomacrodex) daily for the first 3 days.

Postoperative care is in the general surgical ward and is the routine for any abdominal operation. No patient in the extraperitoneal group has required treatment in an intensive therapy unit. Anticoagulants are not used postoperatively. Because the peritoneum is not opened, convalescence is remarkably easy. A nasogastric tube is usually inserted by the anaesthetist during the operation, and in the majority of cases is removed 24 hours later. Limited oral fluids are commenced on the first postoperative day, and are increased with the onset of intestinal activity. The length of stay in hospital after surgery has been shortened by 2 or 3 days but it is our practice to keep the patient in hospital until the twelfth day when the skin sutures are removed. Patients are much more mobile in the early postoperative period and discomfort is little more than that experienced after herniorrhaphy or appendicectomy.

Results

Two hundred and three patients were followed up for this report, 90 having undergone the extraperitoneal operation and 113 being operated on by the transperitoneal approach. One hundred and twenty-five patients (62 per cent) presented with intermittent claudication and the remaining 78 (38 per cent) with severe rest pain or established gangrene. Most of the latter patients had superficial femoral occlusions in addition to their aorto-iliac disease. Severe hypertension was uncommon but some elevation of the diastolic pressure was found in one-third of the patients. Electrocardiographic evidence of coronary artery disease was noted in 25 per cent of all the patients. More than a quarter of the patients were aged over 60 years.

Operative mortality

Seven patients died within 1 month of operation, a mortality rate of 3·5 per cent. Five of the 7 patients had presented with rest pain or gangrene. Three deaths occurred in the extraperitoneal group (90 patients) and 4 in the transperitoneal group (103 patients). The causes of the deaths were: pulmonary embolism 2, cerebrovascular accident 2, coronary thrombosis 1, bronchopneumonia 1, haemorrhage into duodenum 1.

Late postoperative deaths

Forty-three patients (20 per cent) died at intervals between 3 months and 9 years postoperatively, 13 of these having survived for 5 years. Twenty-four (56 per cent) were certified as having died from coronary thrombosis and 5 from a cerebrovascular accident. In 22 of these 43 patients the grafts were patent at the time of death. The low patency rate in this group may well relate to the fact that 32, or three-quarters, of the late deaths were in patients who presented with rest pain or gangrene and had more extensive disease.

Reoperation

Early reoperation was performed on 7 patients in the claudication group in whom re-thrombosis had occurred. Three patients had been treated by the extraperitoneal approach and 4 by the transperitoneal approach. Four were successfully treated by thrombectomy and 3 by some further reconstruction. Late reoperation was performed on 15 patients—8 from the extraperitoneal group and 7 from the transperitoneal group. The operations done were 6 axillofemoral grafts (all of which have subsequently thrombosed), 2 excisions of false aneurysms, 1 thrombectomy and replacement of one limb of a bifurcation graft in 6 patients.

Postoperative complications

The postoperative complications are set out in *Table I*. It will be seen that complications were twice as frequent in the transperitoneal group as in the extraperitoneal group. There have been no haematomas in the groin since Redivac drains have been used. The table cannot convey the much smoother convalescence of patients who have been treated by the extraperitoneal approach.

Table I: POSTOPERATIVE COMPLICATIONS

Complications	Extra-peritoneal group (90 patients)	Trans-peritoneal group (113 patients)	Total (203 patients)
Bronchopneumonia	1	3	4
Coronary thrombosis	1	2	3
Cerebrovascular accident	—	2	2
Deep vein thrombosis (symptomatic)	3	7	10
Pulmonary embolus (symptomatic)	2	5	7
Haemorrhage into duodenum	—	1	1
Paralytic ileus	—	2	2
Wound dehiscence	—	1	1
Retroperitoneal haemorrhage	1	—	1
Incisional hernia	—	3	3
Minor wound sepsis	3	2	5
Haematoma in groin	4	—	4
Femoral aneurysm	—	1	1
False femoral aneurysm	—	2	2
Neuralgic pain	—	2	2
Total	15	33	48

Follow-up

Of the 78 patients presenting with rest pain or gangrene, 24 (30 per cent) came to amputation. Forty-six patients were alive and 35 (86 per cent) of them had relief of symptoms for a year or more, 13 being symptom-free at 4 years and 6 for over 7 years. It seems satisfactory to note that 70 per cent of the painful legs were saved from amputation.

Of the 125 patients presenting with claudication, 13 had died. Only 3 patients lost a limb—2 at 2 years and 1 at 7 years after operation. We decided to report only the results of the 69 patients who had undergone surgery at least 4 years previously. In 62 (89 per cent) of these the reconstructions had remained patent (4 for 13 years, and 12 for over 7 years). However, only 42 patients (61 per cent) were totally symptom-free. The remaining 20 patients (28 per cent) were significantly improved in that some calf claudication was experienced but only after walking fairly long distances. We submit, therefore, that patency rates alone may not indicate complete success of a surgical procedure. The results, not surprisingly, were better in the patients whose disease was mainly confined to the aorto-iliac segment.

Discussion

These results are comparable with those in other series and satisfy us that aorto-iliac reconstruction for atherosclerosis is a worthwhile procedure, bearing in mind that one is dealing with only a part of a generalized, progressive and frequently lethal disease. Certainly the operation, in our hands, is more worthwhile than femoropopliteal grafting procedures. We could find no significant difference in the long term results following the two types of operative exposure. However, both junior doctors and nursing staff agree that the postoperative convalescence of those treated by the extraperitoneal approach is noticeably smoother and easier. Operating time is significantly shortened by this approach, both the exposure and the closure being considerably quicker. This, for us, is an important consideration since these operations were done as part of a normal general operating list.

Oesophagogastrostomy without a drainage procedure in oesophageal carcinoma

I. B. ANGORN*

SUMMARY

Ten patients with carcinoma of the lower third of the oesophagus who had oesophagogastrectomy followed by oesophagogastrostomy without a drainage procedure were investigated 6 months postoperatively. Postoperative symptomatic evaluation and modified Visick grading of the results were carried out by an independent observer. Objective assessment included fibre-optic endoscopy of the oesophagus, stomach and duodenum, gastric acid secretory studies and measurement of gastric emptying times following the ingestion of a barium food mixture.

Eight of the 10 patients had an excellent or very good result and the remaining 2 were graded as satisfactory. No evidence of macroscopic oesophagitis or gastritis was detected and pyloric obstruction was never observed. Gastric emptying time was not prolonged. The results obtained support the concept that a drainage procedure is unnecessary after oesophagogastrostomy.

IT has been generally accepted that oesophagogastrectomy followed by oesophagogastrostomy must be accompanied by a pyloroplasty, because of the incidental vagotomy and resulting gastric stasis. The Heineke–Mikulicz pyloroplasty has been the procedure of choice, but some surgeons perform Ramstedt pyloromyotomy or dilatation of the pylorus as an alternative. Reports exist of clinical series where oesophagogastrostomy has been performed without a drainage procedure (Logan, 1963; Zacho and Fischermann, 1965; Collis, 1971). The majority of these patients have shown no untoward sequelae. Shapiro et al. (1972) reported an experimental study on mongrel dogs and concluded that a drainage procedure is unnecessary after oesophagogastrostomy. Little information is available on the behaviour in humans of the gastric remnant following oesophagogastrostomy without drainage. The present study reports the results obtained from investigating patients in whom the pylorus was left inviolate after oesophagogastrostomy.

Patients and methods

During the period January 1972 to July 1973, 20 patients suffering from carcinoma of the lower third of the oesophagus were submitted to oesophagogastrectomy followed by oesophagogastrostomy without a drainage procedure. A two-phase technique similar to the Ivor Lewis (1946) procedure was employed. Ten of these patients (8 males and 2 females) were evaluated at 6 months after operation.

Symptomatic evaluation

An independent observer ascertained the patients' ability to eat and swallow normally, and inquired for the presence of symptoms which might be referable to the operative procedure. These were: dysphagia, anorexia, nausea, fullness, heartburn, regurgitation, pyrosis, flatulence, dumping, diarrhoea, vomiting. A modified Visick (1948) grading of the results was carried out. Four categories of result are recognized (*Table I*). From a practical point of view categories I and II can be regarded as highly satisfactory.

Table I: GRADING OF RESULTS (MODIFIED VISICK CLASSIFICATION)

Category	Definition
I Excellent	Symptom-free
II Very good	Mild symptoms, but patient considers result perfect
III Satisfactory	Mild or moderate symptoms not controlled by care, but not interfering with work or enjoyment of life. Patient and surgeon satisfied
IV Unsatisfactory	Moderate or severe symptoms compromising work and enjoyment of life. Patient or doctor dissatisfied with result

Endoscopic examination

The oesophagus, stomach and duodenum were examined using the long (120-cm) Olympus GIF end-viewing fibre-optic duodenoscope. The oesophagus was examined for overt reflux and the presence of macroscopic oesophagitis. Oesophagitis was defined and graded according to the criteria of Skinner and Belsey (1967). They defined four categories: grade I, mucosal redness; grade II, isolated scattered superficial ulceration: grade III, chronic ulcer with infiltration and thickening deep to the ulcer; grade IV, stricture. The oesophageal mucosa was biopsied immediately above the anastomotic site.

The stomach was examined to determine the presence of gastritis. Criteria for the diagnosis of gastritis were: mucosal oedema, hyperaemia, excess adherent mucus, petechial or confluent mucosal haemorrhages, erosions and superficial ulcers. The behaviour of the pylorus was observed visually and the nature of gastric peristalsis noted.

Gastric acid studies

Gastric acid output was measured by the method of Kay (1967), except that 6 μg/kg intramuscular pentagastrin were used as a stimulus.

s.d.	0·34	1·4
s.e.	0·10	0·44

BAO, Basal acid output. MAO, Maximal acid output.

Gastric emptying time

This was studied in all 10 patients and compared with normal control subjects and patients who had undergone truncal vagotomy and pyloroplasty for duodenal ulcer who were matched according to age and sex. After an overnight fast a plain X-ray film of the abdomen was taken. Then a semi-fluid meal consisting of 200 ml porridge, 30 ml milk, 30 ml barium suspension and 2 teaspoonfuls of sugar was served warm to all the patients. It was eaten using a spoon with the patient sitting upright in a chair and consumed in 5–10 minutes. Further abdominal X-rays were taken at 15, 30, 120, 180 and 240 minutes with the patient lying in the prone position. In the intervals between exposures the patient was free to sit or walk around the X-ray department. The films were assessed at 15 minutes to detect commencement of gastric emptying and thereafter to ascertain when the stomach was completely empty.

Results

Symptomatic evaluation

The incidence of postoperative symptoms is given in *Table II*. Five of the 10 patients were completely symptom-free. The 2 patients complaining of fullness were able to control this symptom by taking smaller and more frequent meals. They both maintained their weight and considered the result of operation as gratifying. One patient suffered from regurgitation when in the recumbent position, but this was easily controlled by elevating the head end of the bed on two bricks. Two patients both with achlorhydria passed three to five loose yellow stools per day. This symptom was episodic and could be controlled by the administration of tetracycline 1 g daily in divided doses for a period of 3 weeks. *Table III* indicates the overall functional results using a slight modification of the Visick (1948) classification. Eight of the 10 patients (80 per cent) showed an excellent or very good result. The 2 patients in grade III category were in no way compromised by their symptoms.

Endoscopic examination

All 10 patients revealed a healthy distal oesophagus with no evidence of macroscopic oesophagitis. Oesophageal biopsy at the anastomotic site demonstrated microscopic evidence of chronic inflammatory changes in 3 patients. One of these patients complained of regurgitation.

No macroscopic evidence of gastritis was present in any of the patients and reflux of duodenal contents was not observed. The pylorus remained open and patulous a greater percentage of time than normal but was capable of closing spontaneously. Both tonic contraction of the stomach and peristaltic waves occurred during the course of the examination. Antiperistalsis was observed infrequently.

Gastric acid studies

The results of basal acid output (BAO) and maximal acid output (MAO) are summarized in *Table IV*. Two of the 10 patients had absolute achlorhydria and the highest maximal acid output was 5 mEq/h.

Gastric emptying time

Gastric emptying had begun by the time the 15-minute film was exposed in all the patients who had undergone truncal vagotomy and pyloroplasty, but in only 6 of the 10 control subjects and 7 of the 10 patients after oesophagogastrostomy (*Fig*. 1). These differences are not statistically significant.

All the patients who had undergone oesophagogastrostomy and all those who had undergone truncal vagotomy and pyloroplasty showed complete emptying of the stomach at 4 hours. The stomach was completely empty in 7 of the 10 control subjects (*Fig*. 2). These differences are not statistically significant.

Discussion

Following oesophagogastrectomy for carcinoma of the lower third of the oesophagus, alimentary tract continuity is ideally restored by oesophagogastrostomy (Hanna et al., 1967). This procedure has generally been complemented by pyloroplasty because of the incidental vagotomy that is performed. Little evidence exists that pyloroplasty is necessary, and evaluation of our patients indicates that it can safely be omitted.

Symptomatic evaluation by an independent observer 6 months postoperatively revealed that 8 out of 10 patients had a highly satisfactory result. Two out of the 10 patients suffered from diarrhoea (three to five loose yellow stools per day) and weight gain was slow. Both returned to full employment. In all the patients the prime objective of surgery for oesophageal carcinoma, viz. ability to swallow and eat comfortably, was achieved.

Fibre-optic endoscopy of the oesophagus revealed no evidence of macroscopic oesophagitis, but 3 patients, one of whom suffered from regurgitation when recumbent, revealed microscopic changes suggestive of oesophagitis. Allison (1970) stated that oesophagitis may be due to reflux of acid gastric secretions or alkaline duodenal contents. He emphasized that no close correlation exists between the degree of reflux and the frequency and degree of oesophagitis, and that mucosal susceptibility may be a contributing factor. In the present series the absence of symptoms and objective evidence of oesophagitis may be due to three factors. These are: gravity emptying of acid gastric juice, the presence of an intact pylorus preventing duodenal reflux and hypochlorhydria or achlorhydria. It has also been suggested that valvular techniques of oesophagogastric reconstruction may prevent symptomatic reflux (Pearson et al., 1969).

Examination of the stomach revealed no evidence of macroscopic gastritis. The pylorus appeared patulous and remained open a greater percentage of time than normal, but its ability to contract and close spontaneously was still present. Pyloric spasm was never observed. Poorly synchronized peristaltic waves were seen; also infrequent antiperistaltic waves proceeding from the antrum proximally. This desynchronization, as well as diminution in amplitude and duration of peristaltic activity in the vagotomized stomach, has been likened to cardiac atrial fibrillation in slow motion by Nelsen et al. (1967).

Gastric emptying of a food/barium meal measured radiographically is a relatively crude technique. Despite this, two definite observations can be made. The start of gastric emptying can be seen and the time taken for the stomach to empty completely can be ascertained. There was no delay in commencement of gastric emptying in patients following oesophagogastrostomy without pyloroplasty and no prolongation of the complete emptying time. A gastric drainage procedure to prevent gastric stasis is unnecessary, and a high oesophagogastric anastomosis when combined with a drainage procedure has been shown to result uniformly in dumping symptoms (Hanna et al., 1967).

Vagotomy may cause unsynchronized peristaltic waves, not coordinated in time or direction of propagation, resulting in impaired orthograde propulsion of food content (Nelsen et al., 1967). The absence of gastric stasis following oesophagogastrectomy and endothoracic oesophagogastrostomy can be due to various factors. The open or patulous pylorus offers no resistance to gastric emptying. The vertical position of the gastric remnant in the chest allows gravity emptying. Reduction in size of the stomach permits easier filling to capacity, and the full stomach empties at a more rapid rate than the partially filled one due to an increase in mural tension (Hunt, 1959).

Conclusion

Postoperative symptomatic evaluation, endoscopic examination, gastric acid analysis and studies of gastric emptying time in patients who have undergone oesophagogastrostomy without pyloroplasty following oesophagogastrectomy support the concept that a drainage procedure is unnecessary after this anastomosis.

Antrectomy with Roux-en-Y anastomosis in the treatment of peptic oesophagitis with stricture

C. M. S. ROYSTON, B. L. DOWLING AND J. SPENCER*

SUMMARY

A series of 8 patients with severe oesophageal strictures secondary to reflux oesophagitis who have been treated by antrectomy with Roux-en-Y anastomosis is described. There was 1 postoperative death. The remaining patients have been completely relieved of heartburn and all have had a dramatic improvement in their dysphagia. This method of treatment is strongly recommended for patients who have had prior surgery to the hiatus which has failed, and for those who are too elderly or frail to withstand a direct attack on their oesophageal stricture.

REFLUX oesophagitis with stricture formation occurring after previous surgery on the diaphragmatic hiatus presents a difficult surgical problem. A second operation on the hiatus is often a complicated and hazardous procedure, particularly in the elderly, and results are frequently disappointing.

In recent years increasing evidence has accumulated that biliary and pancreatic secretions may be partly responsible for the mucosal damage in reflux oesophagitis. Oesophagojejunostomy after total gastrectomy is often complicated by oesophagitis if a loop of jejunum is used; it was for this reason that the use of a Roux loop was adopted (Kelly et al., 1954; Helsingen, 1960).

Experimental evidence for bile as a causative factor has come from the rhesus monkey studies of Gillison et al. (1972), whilst Lambert's (1962) investigations in the rat have suggested that pancreatic juice may be more important.

Wangenstein and Levin (1949) were the first to observe that reflux oesophagitis could be improved by operations on the stomach. Holt and Large (1961) were the first to employ a Roux-en-Y diversion in the primary treatment of peptic strictures of the oesophagus. They performed this in conjunction with resection of the stricture or extensive resection of the stomach in the majority of their patients. All showed marked improvement in their oesophagitis.

This is a report of a follow-up study of 8 patients with severe strictures of the oesophagus secondary to oesophagitis who have been treated with a limited antrectomy and Roux-en-Y jejunogastric anastomosis without resection of the oesophageal stricture.

Clinical material

The present series consists of 8 patients (mean age 61 years) with severe stricture secondary to reflux oesophagitis. Dysphagia and heartburn were the predominant symptoms in all the patients, 6 of whom had had at least one previous operation on the hiatus.

All the patients first had their strictures dilated with Eder–Puestow dilators (Puestow, 1955), either a few days before operation or on the operating table immediately before the diversion.

Table I summarizes the case histories. The 6 patients who had undergone previous surgery to the hiatus were treated by a limited antrectomy with Roux-en-Y reconstruction (*Fig.* 1). The Roux limb was constructed so that it was at least 45 cm long. In the 2 patients who had not had previous surgery a truncal vagotomy was added as well.

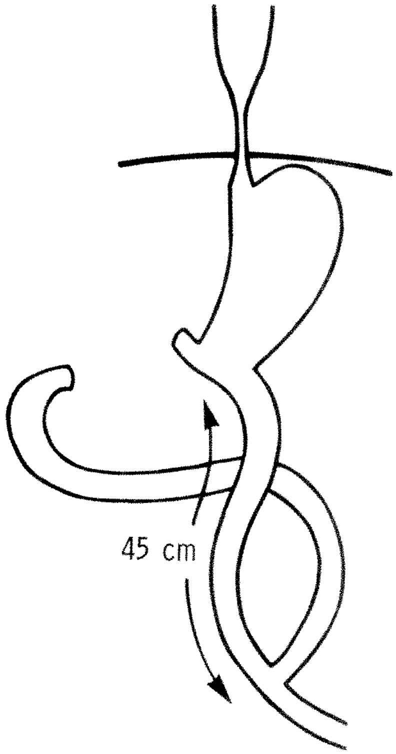

Fig. 1. Diagrammatic representation of the Roux-en-Y diversion procedure.

The following is a typical case history:

E. B., a female aged 70. Symptoms of heartburn started in 1964; these gradually progressed and in 1969 she developed dysphagia to solids. A barium meal examination at this time showed a small sliding hiatus hernia with a stricture at the lower end. Conservative treatment afforded little improvement, so in February 1972 a thoraco-abdominal Collis repair (Collis, 1972) of the hiatus hernia was performed. After this, the patient's dysphagia improved but she continued to suffer from heartburn. In September 1973 dysphagia returned and was rapidly progressive until she could swallow only small volumes of liquid. A barium swallow study (*Fig. 2a*) performed at this time revealed a very tight stricture of the oesophagus, which was confirmed on endoscopy. Marked oesophagitis was present. Initial treatment was conservative, her stricture being dilated with Eder–Puestow dilators. These measures gave temporary relief and in May 1974 an antrectomy with Roux-en-Y diversion was performed. Postoperatively her pain disappeared and her dysphagia rapidly improved, until at 6 weeks she could eat anything. No further dilatations have been necessary. She has now been followed up for 15 months, has gained 12·7 kg in weight and is entirely asymptomatic. *Fig. 2b* shows a barium swallow film 6 months after operation.

* Northampton General and Hammersmith Hospitals, London.

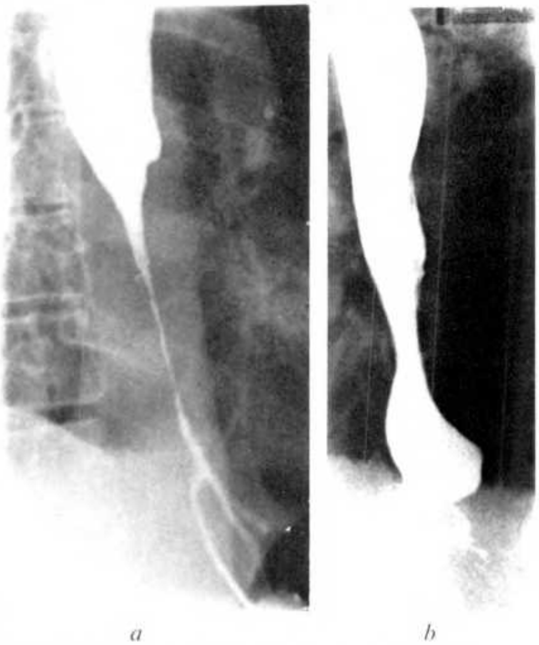

Fig. 2. E. B. Barium swallow films (*a*) before and (*b*) 6 months after the Roux-en-Y procedure.

Results

The follow-up period ranges from 11 to 20 months. One patient who was 74 and very weak and frail before operation died during the postoperative period. Despite intravenous feeding and oesophageal dilatations he remained weak and developed a fulminating bronchopneumonia on the tenth postoperative day. The remaining 7 patients all had complete relief of heartburn after operation. Two were cured of dysphagia without further dilatations. Another 3 were cured after a single dilatation, and 1 patient was dilated twice and is now asymptomatic. The final patient who had a very long history of dysphagia and had been performing self-bouginage for many years has had marked improvement, and can use a larger size bougie at less frequent intervals. He is still improving.

Discussion

Reflux of acid was thought to be the cause of oesophagitis. Recently, however, increasing evidence has accumulated that biliary and pancreatic secretions may be partly responsible for the mucosal damage in reflux oesophagitis. Experimental evidence for bile as a causative factor has come from the rhesus monkey studies of Gillison et al. (1972), who found that reflux of bile and acid caused severe oesophagitis, whereas reflux of acid alone had little effect. Lambert (1962), performing diversionary experiments in Wistar rats, found that pancreatic secretion produced a more

Table I: DETAILS OF THE PRESENT SERIES

Case	Age	Length of history (yr)	Previous surgery	Preoperative state	Result	Follow-up period (mth)

W. H.	74	½	Nil	Dysphagia + +. Small volume of fluid only. Heartburn +	Died postoperatively. Bronchopneumonia	

* Began at 2½ years of age.

marked oesophagitis than biliary secretions, but the combination of biliary and pancreatic secretions caused the more severe oesophageal changes. Studies in man by Gillison et al. (1969) have shown that the symptom of heartburn is associated with reflux of duodenal contents into the stomach and oesophagus. Crumplin et al. (1974) investigated bile salts in the stomach of patients with symptomatic hiatus hernia and of control subjects. They found an increased incidence of bile salts in the stomach following a meal in patients with hiatus hernia, but there was no single constituent of the bile that was more prevalent.

Wangenstein and Levin (1949) were the first to observe that oesophagitis could be improved by operations on the stomach. They reported 6 patients with severe oesophagitis and stricture of the lower oesophagus who after high subtotal Polya gastrectomy showed a marked improvement in their symptoms. Similarly, Tanner and Westerholm (1968) reported a series of 22 patients who underwent a modified Balfour gastrectomy for peptic stricture of the lower oesophagus; all had marked improvement in their symptoms. Cenni et al. (1966) described 3 patients who developed severe oesophagitis following Polya gastrectomy. All were relieved of their symptoms by Roux-en-Y conversion.

Holt and Large (1961) were the first to employ a Roux-en-Y diversion in the primary treatment of peptic strictures. They reported 10 cases of stricture that were treated by distal gastrectomy with Roux-en-Y jejunogastric anastomosis. In 4 of the patients the stricture had occurred following a Grondahl procedure for achalasia. Four of the 10 cases also had a resection of the stricture, and 9 out of 10 had an extensive resection of the stomach. All showed marked improvement in their oesophagitis. Weaver et al. (1970) have recently reported the 8–17-year follow-up of these patients, in all of whom the improvement has been maintained. Payne (1970) reported a series of 15 patients with severe oesophagitis, 13 of whom had a hemigastrectomy with Roux-en-Y diversion performed. Six of these patients had a severe stricture of the oesophagus which was resected; all showed marked improvement.

In the series reviewed, when Roux-en-Y diversion was used for the treatment of oesophageal strictures it was in most cases performed in combination with either resection of the stricture or very extensive subtotal gastrectomy. In our series dramatic improvement in the severity of the dysphagia occurred despite the presence of an apparently tight fibrous stricture. The most striking feature in our series was the complete relief of heartburn; none of the patients had any heartburn from the day of operation onwards. The improvement in the dysphagia was much slower, often taking 2–3 months before marked improvement occurred. This latter observation was confirmed on endoscopy. In the patients undergoing endoscopy soon after operation little change was apparent; however, after 3 months mucosal appearances had returned to normal.

Gastric mucosal resection in the treatment of peptic ulcers: a 1–10 year clinical follow-up

R. M. KIRK*

SUMMARY

The clinical results of gastric mucosal resection are reported after a 1–10-year follow-up in which 76 per cent of patients were followed up for more than 5 years. There were 3 postoperative deaths in 152 patients. Mucosal antrectomy with vagotomy for duodenal ulcer in 96 patients, and for recurrent ulcer in 9 patients, has not been followed by a single recurrence. Gastric mucosal resection alone for the treatment of gastric ulcer in 21 patients resulted in 1 recurrence.

Although vagotomy combined with resection is currently out of fashion for the initial treatment of duodenal ulcer in Britain, mucosal gastric resection has technical advantages in combination with vagotomy for the cure of recurrent ulcers following duodenal ulcer surgery.

MUCOSAL gastric resection is a form of gastrectomy in which the mucosa alone is excised, leaving the other layers of the stomach wall intact. The raw areas are folded away so that mucosal continuity is restored. Mucosal excision is accomplished through a gastroduodenotomy which is then closed after the fashion of a Heineke–Mikulicz pyloroplasty (Kirk, 1965, 1966; Kirk and Sussman, 1972).

Technique

For the treatment of duodenal ulcers mucosal antrectomy is preceded by truncal or selective vagotomy. The extent of mucosal resection for gastric ulcer is equivalent to the formal excision accomplished by Billroth I gastrectomy. When treating recurrent ulcer mucosal antrectomy is combined with truncal vagotomy or the completion of vagotomy.

Gastric mucosal resection is carried out through a gastroduodenotomy. The distal gastric submucosa is infiltrated with an adrenaline in saline solution. The mucosa of the distal stomach is excised, and bleeding points are sealed with diathermy. The posterior gastric and duodenal mucosal edges are then stitched edge to edge, folding the denuded portion of stomach wall backwards. The anterior walls are closed in the manner of a Heineke–Mikulicz pyloroplasty. The raw surfaces are thus excluded so that gastroduodenal mucosal continuity is re-established.

Follow-up

Contact was maintained by requesting patients to post a card annually stating their condition. Symptomatic patients were sent an outpatients' clinic appointment. A comprehensive questionnaire was sent out at 3-yearly intervals. All the patients were assessed independently once or more frequently at least a year after operation. Because the operations were carried out at five widely separated hospitals it was not possible to use a single assessor. For the same reason the final interview was conducted by the author.

Seventeen patients were submitted to acid secretion studies after periods of more than a year after operation. Further operations were performed on 3 patients.

Clinical results were graded by the modified Visick scale described by Goligher et al. (1968). Grade 1 patients were completely asymptomatic. Grade 2 patients had good results but with minor symptoms, easily controlled by dietary adjustments. Grade 3 patients had mild or moderate symptoms not controlled by simple measures. Grade 4 patients had unsatisfactory results because of moderate or severe symptoms or complications which interfered with enjoyment of life or capacity to work. All the patients requiring further surgical procedures were included in this category.

Results

There were 3 (2 per cent) postoperative deaths in 152 patients, from cardiac or respiratory complications. Postoperative bleeding and suture line leaks were not encountered. Subsequent deaths were unrelated to the operation except for a single patient who developed gastric carcinoma after 6 years.

The interval between operation and final interview is set out in *Table I*, together with the number of patients lost from the series. Of 129 patients followed up, 98 (76 per cent) had been operated upon more than 5 years before, and all the primary operations for duodenal ulcers had been carried out at least 3 years before assessment.

There were no recurrences following vagotomy and mucosal antrectomy for the treatment of duodenal ulcers. Also, the combination was effective in the treatment of recurrent ulcers following duodenal ulcer surgery. One patient had recurrence of a gastric ulcer following gastric mucosal resection alone.

The grading of the clinical results is set out in *Table II*. Following vagotomy and mucosal antrectomy for duodenal ulcer in 96 patients, 81 (84·4 per cent) were placed in categories 1 or 2. It was noted during the serial assessment that patients seemed to reach a stable state within 1 year in terms of postoperative symptoms; those with severe symptoms either improved slowly or became more tolerant of

As conversion procedure	DU*			3		3
Total	75	75	33	18	3	129

DU, Duodenal ulcer. GU, Gastric ulcer. RU, Recurrent ulcer
* Conversion followed primary duodenal ulcer operation.

them. None of the patients changed substantially after 2 years, even when they were followed up for 10 years.

One patient had such severe postprandial colic and dumping following truncal vagotomy and mucosal antrectomy that he was re-explored, but no cause was found. A patient with quiescent terminal ileitis developed incapacitating diarrhoea following selective vagotomy and mucosal antrectomy, although there was no evidence of recrudescent Crohn's disease. Three patients complained of episodic diarrhoea following truncal vagotomy. Moderate dumping symptoms followed 14 primary and 4 revision operations.

Of 17 patients submitted to insulin tests of gastric secretion at least 1 year after vagotomy and mucosal antrectomy, 16 had negative tests and 1 showed a late positive result.

Discussion

Vagotomy combined with mucosal antrectomy has been an effective combination for the initial treatment of duodenal ulcer, since there was not a single recurrence in 96 patients. It appears to be as effective as vagotomy combined with formal antrectomy in guarding against recurrence, and it results in a low incidence of positive insulin tests (Jordan and Condon, 1970). The Visick grading results are similar to those reported by Goligher et al. (1968) for vagotomy and formal antrectomy, with 84·4 per cent of the patients in the present series falling into categories 1 and 2.

However, Johnston (1974) reported not a single recurrence following 350 operations of highly selective vagotomy (proximal gastric vagotomy) carried out in Leeds and Copenhagen for duodenal ulcers. Kirk (1975) has had 2 recurrences out of 57 patients. Johnston (1975) has emphasized the very low mortality associated with highly selective vagotomy. Unless the long term results of proximal gastric vagotomy without drainage are disappointing, it is likely to become even more popular for the initial surgical treatment of duodenal ulcer.

In the treatment of recurrent ulcer, vagotomy, or completion of vagotomy, combined with mucosal antrectomy, has been effective in curing 9 patients. It has a technical advantage in patients who have previously been submitted to gastric surgery that the mucosal resection can be performed entirely from within the stomach without the need to ligate and divide a single major blood vessel.

Abdominal tuberculosis: demonstration of tubercle bacilli in tissues and experimental production of hyperplastic enteric lesions

PRITAM DAS AND H. S. SHUKLA*

SUMMARY

Material obtained from 35 cases of abdominal tuberculosis was studied and an attempt was made to demonstrate tubercle bacilli by special staining of histological sections, culture and guinea-pig inoculation.

Acid fast bacilli could be demonstrated in 80 per cent of cases. The remaining cases were also possibly due to tuberculous infection because granulomas with Langhans's type of giant cells and caseation or calcification of lymph nodes were present. The bacilli were demonstrated in bowel tissue showing non-specific histology in 1 case. In 2 other cases with non-specific lesions in the bowel the bacilli were demonstrated in lymph nodes.

Guinea-pig inoculation studies showed that hypertrophic lesions of the bowel with a non-specific type of reaction could develop after intraperitoneal injection of tubercular material.

Although it cannot be said on the basis of this study that Crohn's disease is caused by tuberculous infection, it can be concluded that tuberculous infection can give rise to a Crohn's type of lesion.

SINCE Crohn et al. (1932) described regional ileitis a controversy has arisen and many have doubted even the existence of hyperplastic enteric tuberculosis. Warren and Sommers (1948), Manglik and Misra (1952) and Gupta et al. (1962) came to the conclusion that the so-called ileocaecal tuberculosis was a non-specific granulomatous lesion. They were unable to demonstrate tubercle bacilli in any of their specimens. Taylor (1945), Anand (1956), Bruce (1959), Paustian and Bockus (1959) and Chandra and Basu (1967) presented the opposite view and doubted if regional ileitis was a separate pathological process. Taylor (1945) considered hyperplastic ileocaecal tuberculosis and regional ileitis to be different responses of the host to infection with tubercle bacilli, and Anand (1956) opined that bowel changes in regional ileitis may well be due to modification of tubercular enteritis by anti-tubercular drugs, increased host resistance and low virulence of organisms. Florey (1954) observed that productive tubercular lesions without caseation may occur in patients with low sensitivity and high immunity to tubercle bacilli. Reiks and Washington (1962) and Prakash et al. (1970) observed that an atypical strain of mycobacteria may produce a variable morphological picture in the intestine. The differentiation between these two conditions on clinical grounds, and even on histological examination of resected tissues, is difficult, as reported by many workers (Anderson and Munro, 1932; Crohn and Yarnis, 1940; Tribedi and Gupta, 1941; Ukil, 1942; Warren and Sommers, 1948; Taylor, 1945; Hoon et al., 1950; Anand, 1956; Brenner et al., 1970; Tandon and Prakash, 1972). Therefore, the demonstration of tubercle bacilli in the tissues assumes utmost importance in the diagnosis of these lesions.

In the present study an attempt was made to identify the tubercle bacilli in the tissues on histological examination, by culture of the tissues and by guinea-pig inoculation. Typing and drug sensitivity of the bacilli were also done. During this investigation hyperplastic intestinal lesions were discovered in guinea-pigs.

Materials and methods

Material removed from 35 patients with abdominal tuberculosis admitted to SRN Hospital, Allanhabad, India, during 1973 was studied. Immediately after removal of the tissue, specimens for culture and guinea-pig inoculation were deep frozen, while the rest was placed in 10 per cent formol saline. The following examinations were subsequently carried out:

1. *Histological examination* of resected tissues or biopsy specimen was done in 66 cases: mesenteric nodes 18, bowel 10, peritoneum 21, omentum 3, cold abscess wall 1, liver biopsy 8 and endometrium 5. Paraffin sections were prepared using xyline as clearing agent. The sections were stained with haematoxylin and eosin.
2. *Demonstration of acid fast bacilli in tissue sections*: Fifty-one specimens were stained by the modified Ziehl–Neelsen method (Cruickshank, 1970) for demonstration of tubercle bacilli.
3. *Culture of acid fast bacilli*: Petroff's modified method (Cruickshank, 1970) was employed for concentrating tubercle bacilli in tissues. Inoculation was done on Lowenstein–Jensen medium. Cultures were made from 31 samples: mesenteric lymph nodes 11, bowel 7, ascitic fluid 8, wound discharge 1, peritoneum 2, omentum 2.
4. *Guinea-pig inoculation* was performed with tissue concentrate prepared for culture as above from 19 samples: mesenteric nodes 4, bowel 8, peritoneal fluid 4, peritoneum 3. The concentrate was injected intraperitoneally and each animal was kept strictly isolated

*Department of Surgery, MLN Medical College, Allahabad, India.

for 6 weeks, when they were sacrificed. Five animals died within 2 weeks. Autopsy was done in all the animals and viscera were examined for tubercular lesions by naked eye and microscopic examination. Tissue sections were stained for tubercle bacilli.

5. *Drug sensitivity* was tested in 14 cases by the method of Cruickshank (1970) against streptomycin, isonicotinic acid hydrazide, para-aminosalicyclic acid, ethambutal, cycloserine and thiosemicarbazone.

6. *Type verification of Mycobacterium tuberculosis* into human, bovine and anonymous varieties was done in 14 cases by the method of Marks (1964) and Cruickshank (1970) on the basis of growth on Lowenstein–Jensen medium, catalase activity, drug sensitivity and reaction in guinea-pigs. Growth of the organisms was observed in normal light at room temperature, 37 °C and 43 °C, and in complete darkness at 37 °C.

Observations

The various lesions observed clinically or at laparotomy were stricture of the ileum 8, hyperplastic caecal lesions 3, stricture of the colon 2, mesenteric lymphadenitis 2, chronic tuberculous peritonitis 14 and tuberculous ascites 6, giving a total of 35 lesions. The grouping was done according to the dominant lesion observed clinically or at the time of operation.

Bowel lesions

Of the 13 cases in which bowel was involved, a resected bowel specimen along with mesentery was available in 10, lymph nodes only in 2 and a piece of peritoneum alone in 1 case. Naked eye examination showed a few unusual features worthy of note.

1. Mesenteric fat was increased in all cases; in some the fat extended on to the bowel, a feature which has been described as typical of regional ileitis (Valdes-Dapena, 1966).

2. In 2 cases the mucosal ulcer crater had become epithelialized.

3. In 1 case a pseudopolyp was present at the site of the stricture.

4. Small superficial ulcers were present on the mucosa proximal to the site of lesion in 4 cases (*Fig.* 1). These lesions have also been described as typical of regional ileitis (Valdes-Dapena, 1966).

Histological examination of the bowel showed a tubercular granuloma with caseation in 2 cases, granuloma with giant cells but no caseation in 4 and a non-specific type of granuloma without caseation and without giant cells in 4 cases (*Table I*). Some of the unusual features on histological examination of the bowel were:

1. The three types of granuloma could be seen on the same slide at different places (*Fig.* 2), indicating that any one of the three types of histological picture could be produced by tubercular infection of the bowel.

2. Granulomas were found in the submucous as well as in the muscle layer.

3. Diffuse infiltration of chronic inflammatory cells as opposed to localized granulomas was also present in all the bowel layers in positively tubercular lesions.

4. Granulation tissue could be seen extending from the mucosa to the serosa in some of the slides (*Fig.* 3).

5. All the 4 cases showing a non-specific type of lesion had had anti-tubercular treatment prior to operation.

Table I: HISTOLOGICAL AND BACTERIOLOGICAL FEATURES OF BOWEL LESIONS

Case no.	Specimen	Microscopic examination			AFB in tissues	AFB on culture	AFB on guinea-pig inoculation	Previous anti-tubercular treatment
		Bowel	Lymph node	Peritoneum				
15	Stricture of ileum	Granuloma with giant cells	Caseation present		Bowel+ Lymph node−	Bowel− Lymph node−	Bowel+	No
16	Stricture of ileum	Granuloma with caseation	Caseation present	Caseation present	Bowel+ Lymph node+ Peritoneum+	Bowel+ Lymph node−	Not done	No
17	Stricture of ileum		Granuloma with giant cells		Lymph node−	Not done	Not done	No
19	Stricture of ileum	Non-specific granuloma	Calcified		Bowel− Lymph node−	Bowel− Lymph node−	Bowel−	Yes
20	Stricture of ileum		Caseation present	Non-specific granuloma	Lymph node+	Not done	Not done	Yes
31	Stricture of ileum	Granuloma with giant cells. No caseation			Bowel−	Bowel+	Animal died early	No
34	Stricture of ileum	Non-specific granuloma	Caseation present		Lymph node+ Bowel−	Bowel−	Bowel−	Yes
37	Stricture of ileum			Granuloma with giant cells	Peritoneum−	Peritoneal fluid+	Not done	No
24	Hypertrophic caecum	Non-specific granuloma	Granuloma with giant cells		Bowel+ Lymph node+	Bowel− Lymph node+	Bowel−	Yes
29	Hypertrophic caecum	Non-specific granuloma	Granuloma with giant cells		Bowel− Lymph node−		Bowel−	Yes
33	Hypertrophic caecum	Granuloma with caseation	Granuloma with giant cells		Bowel+ Lymph node−	Lymph node+	Lymph node+	No
2	Stricture of colon	Non-specific granuloma	Caseation present	Normal	Bowel− Lymph node+	Bowel−	Died early	Yes
25	Stricture of colon	Granuloma with giant cells	Caseation present		Bowel− Lymph node+			No

AFB, Acid fast bacilli: +, bacilli present; −, bacilli absent.

Tubercle bacilli were demonstrated in the bowel in 3 cases on histological examination, culture of tissue or guinea-pig inoculation (*Table I*). In the other 5 bowel specimens the tubercle bacilli could not be demonstrated in the bowel wall but they were demonstrated in the lymph nodes in 2 and in the peritoneal fluid in 1. Thus, there were 2 cases in which tubercle bacilli were not demonstrated in any of the tissues examined. In one the lymph node examined was calcified, and in the other a granuloma with giant cells was present in the lymph node. Both these cases had a non-specific lesion in the bowel.

Of the 3 cases of bowel involvement in which a resected bowel specimen was not available, one showed tubercle bacilli in a lymph node, one had tubercle bacilli in the peritoneal fluid and in one there was a giant cell granuloma in a lymph node but no tubercle bacilli could be demonstrated.

Mesenteric lymphadenitis

Tuberculous mesenteric lymphadenitis without any obvious bowel lesion was present in 2 cases (*Table II*); both of them presented as cold abscesses in the mesentery. Histological examination showed a tubercular granuloma with caseation in one case, and a granuloma with giant cells but no caseation in the other. Acid fast bacilli were demonstrated in the tissues in both cases. Neither had had anti-tubercular treatment before operation.

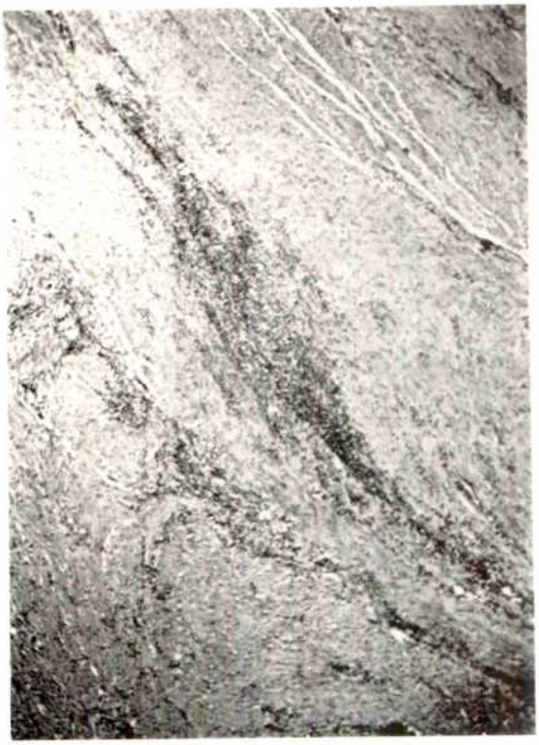

Fig. 3. Photomicrograph of a bowel lesion showing extension of granulation tissue from mucosa to serosa.

Table V: POSITIVE CULTURES IN TISSUES AND FLUIDS

Tissue or fluid cultured	Total no.	No. in which AFB grown	%
Mesenteric lymph nodes	11	6	54·5
Bowel	7	2	42·8
Ascitic fluid and wound discharge	9	4	44·4
Peritoneum/omentum	4	2	50·0
Total	31	15	48·4

Chronic miliary tuberculous peritonitis

There were 14 cases in which the dominant feature on opening the abdomen was the presence of widespread multiple tubercles on the peritoneal surface. There was no apparent lesion of the bowel. Lymph node enlargement was also not a dominant feature. A piece of peritoneum was available in 11 cases, lymph nodes in 4, needle biopsy of the liver in 4, a piece of omentum in 3 and peritoneal fluid in 1. In the 3 cases in which a piece of peritoneum was not available, wound discharge was available in 1, a lymph node in 1 and omentum in the third case.

Histological examination of the peritoneal pieces showed caseation in 3 cases, a granuloma with giant cells in 5 and a non-specific granuloma in 3 cases. Liver biopsy showed caseation in 1, fatty change in 2 and normal parenchyma in 1 (*Table III*). The omentum showed granuloma with giant cells.

In the 14 cases of chronic miliary tuberculous peritonitis, tubercle bacilli were demonstrated in 12 cases (*Table III*), including 3 cases in which the histological picture was of non-specific inflammation. The wound discharge and the peritoneal fluid were positive for acid fast bacilli. In the remaining 2 cases acid fast bacilli were not demonstrated in any specimen; one had a granuloma with caseation in the peritoneum and the other showed a granuloma with giant cells on omental biopsy. Unfortunately guinea-pig inoculation was not done in one of these cases and guinea-pig inoculation and culture were not done in the other case.

Ascites

In this group 6 cases with fluid distension of the abdomen were included. Biopsy samples of peritoneum were available in 5 cases along with ascitic fluid in 5, needle biopsy of the liver in 2 and a lymph node in 1 case. Ascitic fluid was available in the case for which there was no peritoneal biopsy.

Histology of the peritoneal biopsy showed caseation necrosis in 1 and granuloma with giant cells in 4 cases. The lymph node showed caseation. This was the same case in which the peritoneum had shown caseation (*Table IV*).

Tubercle bacilli were demonstrated in a lymph node in 1 case and in the ascitic fluid in 3 cases. The 2 cases in which tubercle bacilli were not demonstrated had granulomas with giant cells on histological examination (*Table IV*).

Culture results

Of the 31 specimens cultured, 15 (48·4 per cent) yielded positive results (*Table V*). The bowel yielded the least percentage of positive cultures (2 out of 7), while the mesenteric nodes and peritoneal fluid yielded positive results in 6 out of 11 and 4 out of 9 cases respectively. It has to be emphasized that 4 of the 7 bowel cases had had anti-tubercular treatment, and 2 of the 3 cases who had had no anti-tubercular treatment yielded a positive bowel culture.

Typing of the acid fast bacilli

Thirteen of the 14 cultures tested were found to be of the human variety. In 1 case the bacilli grown from ascitic fluid were the anonymous type.

Drug sensitivity

Drug sensitivity was tested in 14 cultures (*Table VI*). The bacilli were resistant to streptomycin in 8, to para-aminosalicyclic acid in 8, to ethambutal in 4, to isonicotinic acid hydrazide and cycloserine in 1 each and to thiosemicarbazone in none. Surprisingly, 11 of these patients had had no anti-tubercular treatment, and in the 1 patient who had received anti-tubercular treatment the bacilli were sensitive to all these anti-tubercular drugs except para-aminosalicylic acid, which she had not been given.

Guinea-pig inoculation

Nineteen guinea-pigs were inoculated with tissue extract. Five of these died within 1–2 weeks, before the tubercular lesion had had time to develop. Of the remaining 14 animals, 10 developed tubercular lesions and 4 did not. Nine cases which showed a positive guinea-pig test were also positive on tissue culture or acid fast staining of tissue sections. One case was positive on guinea-pig inoculation alone so that guinea-pig inoculation did add to the diagnostic accuracy to a small extent. There were 2 cases in which the guinea-pig inoculation of the bowel was negative while the histological section showed tubercle bacilli.

The various lesions found in the guinea-pigs are shown in *Table VII*. It can be observed that none of the animals developed a lesion in the peritoneum, 8 showed caseous mesenteric nodes, 4 had caseous tubercles in the liver and 8 had caseous tubercles in the spleen. An interesting feature was the development of hyperplastic intestinal lesions in the bowel in 4 animals. The segment of the terminal ileum involved was 3–5 mm in length. The bowel was visibly and palpably thickened and histological examination showed a non-specific lesion. Two showed tubercle bacilli in these lesions on acid fast staining, and the mesenteric nodes were positive for acid fast bacilli. The significance of this observation is considerable in that the hypertrophic bowel lesion could occur from infection from the peritoneum, and these lesions may or may not show the organisms. The tubercle bacilli were seen in large numbers in tissues of guinea-pigs and the bacilli were comparatively longer.

Discussion

Bowel lesions

There were 4 specimens of bowel in which the microscopic picture was of the non-specific type. These patients had had anti-tuberculous treatment for periods ranging from 27 days to 2 years. In 2 cases tubercle bacilli were seen on the histological section of

Granuloma with giant cells. No caseation necrosis	20	8	40
Granuloma with caseation necrosis	20	16	80
Total	51	29	56·8

a regional lymph node. In the other 2 no tubercle bacilli were demonstrated by histological section, tissue culture or guinea-pig inoculation. These cases could be regarded as regional enteritis. We are inclined to believe them to be tuberculous because in one a regional lymph node showed a granuloma with giant cells, and in the other the lymph node was calcified. Several workers have reported that anti-tubercular therapy alters the histology to a non-caseous granuloma (Taylor, 1945; Wig and Bawa, 1953; Anand, 1956). In addition to these observations, we have to add that a caseating granuloma and a non-specific type of granuloma may be present on the same histological slide of bowel. Confluent granulomas and transmural infiltration of bowel wall, which are more frequent in tuberculosis than in Crohn's disease (Howell and Knanpton, 1964; Hawley et al., 1968), were also observed in our cases. We cannot say that Crohn's disease is caused by infection of tubercle bacilli, but tuberculous infection can cause an inflammatory reaction similar to that of Crohn's disease.

Demonstration of acid fast bacilli

We have been able to demonstrate tubercle bacilli on histological slides in 80 per cent of tissues showing caseation, in 40 per cent of tissues showing granuloma with giant cells and in 45·4 per cent of tissues showing non-specific granuloma (*Table VIII*). The tubercle bacilli in the tissues showed variable morphology. Some of them were long and beaded, some were short and straight and others were long and curved. In caseous areas the bacilli were seen in and around the area of caseation. The bacilli were sparsely distributed and required prolonged search. Anand (1956), Hancock (1958), Howel and Knanpton (1964) and Lee and Roy (1964) showed that there is no correlation between caseation and positive culture growth. This was not so in our cases. Wig and Bawa (1953) obtained growth of tubercle bacilli in 26 out of 88 cases, and Prakash et al. (1974) obtained growth in 11 out of 95 cases. In our study we were able to obtain a positive culture in 15 out of 31 specimens, probably the highest figure obtained so far by any worker. Six out of 11 mesenteric nodes and 2 out of 7 bowel specimens showed a positive culture growth in our cases.

Considering all the examinations done, we were able to demonstrate tubercle bacilli in 28 (80 per cent) out of 35 cases studied. A more thorough search could have resulted in a higher incidence of positive results. Culture or guinea-pig inoculation was not done in all cases, and these procedures might have yielded tubercle bacilli.

Experimental production of hyperplastic lesions

Attempts have been made to produce abdominal tuberculosis in guinea-pigs. Oral feeding with infected material results in the production of ulcerative intestinal lesions. Klebs (1868) and Anguli and Menon (1950) produced bowel lesions by feeding guinea-pigs with infected material. They also removed the regional lymph nodes and came to the conclusion that lymphatic obstruction resulted in non-specific ulceration of the bowel segment concerned and an increase in subserous fat. The intraperitoneal injection of tubercular material results in infection of the liver, spleen, lymph glands and lungs. We have not come across any report describing bowel lesions after intraperitoneal injection. It was therefore of considerable interest when hypertrophic intestinal lesions were detected in the present study in 4 of the animals. Histological examination of these lesions showed a non-specific type of response. Acid fast staining of the sections yielded tubercle bacilli in 2. In the other 2 animals acid fast bacilli were detected in the regional lymph nodes. It is evident from these findings that tubercle bacilli can cause a hypertrophic lesion of the bowel with a non-specific type of inflammatory reaction. Further, the organism may or may not be detected, and the infection may not come from the lumen of the bowel. This observation also lends support to the idea that the caecal lesion may be produced by infection from the Fallopian tubes.

The type and resistance of the organisms

Contrary to the belief that bovine infection should be more frequent in bowel lesions, it was found that all the organisms detected in the bowel in this study were of the human type. Only 1 case had mycobacteria of anonymous type, which is reputed to be rarely pathological. It was found in the ascitic fluid.

The organisms were resistant to the various anti-tubercular drugs even in patients who had never had treatment with any of these drugs. Obviously they were resistant from the very beginning. Apparently isonicotinic acid hydrazide gives rise to minimal resistant types, because only 1 case had organisms resistant to this drug, in spite of the fact that it has been in use for more than two decades.

Primary gastric tuberculosis: a case report

R. E. PAGE, R. E. WILLIAMS AND E. A. BENSON*

SUMMARY

A case of primary gastric tuberculosis is reported in a 34-year-old Negro male. The difficulty in diagnosis is emphasized. Surgical resection with postoperative anti-tuberculosis chemotherapy was followed by satisfactory recovery.

Case report

A 34-year-old West Indian labourer, resident in the United Kingdom for 13 years, attended his general practitioner complaining of dyspepsia, and was treated with antacids for a year before a small haematemesis resulted in a surgical outpatients' consultation. A barium meal examination failed to demonstrate any abnormality and the patient was given a further supply of antacids. He was followed up in the outpatients' clinic and continued to complain, and 10 months later when reviewed he had obviously lost weight and examination revealed a gastric succussion splash. A repeat barium meal study (*Fig.* 1) now showed a constant filling deformity in the antral region; no ulcer crater could be identified. A chest X-ray was normal. The patient was admitted to hospital, and at gastroscopy a flat sloughing lesion in the pyloric antrum was visualized but its nature was obscure. Laparotomy revealed a firm infiltrating lesion, low on the lesser curve of the stomach in association with marked lymph node enlargement around the coeliac axis and the left gastric artery; similar enlarged nodes were found in the subpyloric region. In the terminal ileum an infiltrating lesion measuring slightly less than 1 cm in width encircled the bowel. An operative diagnosis of carcinoma of the stomach with secondaries in the terminal ileum was made, and what was felt to be palliative surgery took the form of partial gastrectomy (resecting the gastric lesion but leaving many involved glands around the coeliac axis) together with a small bowel resection.

The pathologist submitted the following report: 'Two specimens were received, firstly a funnel of stomach 11 × 11 cm bearing an ulcer 2 cm in diameter. The adjacent lymph nodes were enlarged and contained creamy material. Secondly, a tube of small intestine 35 cm long × 5 cm diameter with a haemorrhagic fusiform swelling 1 cm in diameter encircling and extending through the wall.

'Microscopy of both specimens showed an acute and chronic inflammatory reaction with, in places, collections of epithelioid cells and Langhans's giant cells (*Fig.* 2). In addition, the lymph nodes showed caseous necrosis (*Fig.* 3).

'Staining of the sections by an auramine phenol fluorescent technique (Greenwood and Fox, 1973) showed the presence of tubercle bacilli in the lesion. These were not confirmed using the Ziehl–Neelsen method.

'In view of the histological picture and fluorescent microscopy a diagnosis of tuberculosis was made. Unfortunately, bacteriological confirmation was not possible as only formalin-fixed material was received (Walter and Israel, 1974).'

The patient was started on streptomycin 0·750 g daily and Mynah 250 (ethambutol and isoniazid) 1 tablet t.d.s., and postoperatively made satisfactory progress and was discharged to a convalescent hospital on the twelfth day. A Mantoux test performed postoperatively was positive, but stool examination did not show any acid-fast bacilli. A repeat chest X-ray failed to demonstrate any pulmonary tuberculosis, and three early morning specimens failed to produce any tubercle bacilli.

The patient was well and gaining weight when seen 4 months after his operation.

Discussion

Primary tuberculosis of the stomach is surpassed in rarity only by a primary lesion involving the oesophagus. Isolated cases of tuberculosis limited to the stomach have appeared in the Russian (Kuzionov and Polinkova, 1973) and Indian (Wig et al., 1961) literature, but in the Western world the condition is extremely rare. The only case of primary gastric tuberculosis to be reported in the Western literature has been by Stirk (1968). Palmer (1950), in 20 585 post-mortem examinations performed on patients dying with pulmonary tuberculosis, found the stomach to be involved in only 0·5 per cent, and in a recent series from South Africa (Novis et al., 1973) only 1 of 59 patients with gastro-intestinal tubercle had involvement of the stomach.

Tuberculosis of the stomach is usually secondary to a primary focus involving another organ, invariably the lungs (Palmer, 1950), and tends to be a feature of widespread disease. The case presented in this communication had no pulmonary or pharyngeal involvement.

The incidence of pulmonary disease diagnosed radiologically in patients with established gastro-intestinal tuberculosis varies from series to series. Hamandi and Thamer (1965), in a study of 86 patients with gastro-intestinal tuberculosis, found only 10 with pulmonary involvement, whereas Novis et al. (1973) demonstrated a pulmonary lesion in 20 out of 56 patients. Abrams and Holden (1964) showed that 56 per cent of patients with pulmonary tuberculosis also have involvement of some part of the gastro-intestinal tract.

The factors protecting the stomach against invasion by tubercle bacilli have been listed by Good (1931). It has, however, been suggested by Kossick (1969) that the organism gains entry to the submucosa of the stomach via a pre-existing ulcer. The patient presented in this communication might conceivably be an example of this.

The radiological appearance of gastric tuberculosis is very similar to that of neoplasia. Indeed, Gaines et al. (1952) felt that radiology had little to offer in arriving at a specific diagnosis of gastric tuberculosis. Our case supports this opinion.

Aird (1958) stated that gastric tuberculosis may rarely be the seat of a carcinoma, and Rentschler and Travis (1934) reported a case of gastric tuberculosis with a sarcoma. In the patient presented here there

was no histological evidence of neoplasia. The association is of interest, however, in that gastric neoplasia produces a state of debilitation, and in the presence of achlorhydria conditions would be theoretically ideal for tuberculous infection.

Stirk (1968) suggested treatment by partial gastrectomy where the lesion exists as a solitary ulcer. This procedure was followed, with success, in our patient. A course of anti-tuberculous drugs should be commenced as soon as the diagnosis is made, otherwise complications may ensue (Iles and Emerson, 1974).

Your hands are your most important instruments-it pays to take care of them

The obvious fact that a surgeon's hands are of prime importance to his work was borne in mind when 'Hibiscrub' was formulated. 'Hibiscrub' is designed to keep hands healthy, even after repeated use.

However, the prime importance of a handwash is effectiveness: rapid prolonged bactericidal action against skin bacteria is assured by the presence of the well-proven antiseptic 'Hibitane'.

"These studies have shown that a 4% chlorhexidine detergent solution ['Hibiscrub'] is a potentially outstanding addition to the small list of detergent-disinfectant preparations for the hands of surgeons and nurses, with a greater immediate effect than that obtained with the hexachlorophane or even the iodophor preparations."
British Medical Journal, (1973), 1, 510.

Congenital hepatic fibrosis: aspects of diagnosis and surgical management

G. S. SOKHI, J. J. MORRICE, J. O'D. McGEE AND L. H. BLUMGART*

SUMMARY

Five cases of congenital hepatic fibrosis are described. In all the patients the diagnosis was delayed as a result of either failure to perform liver biopsy or misinterpretation of the histological features. Four patients had multiple operations for the control of haematemesis or the relief of portal hypertension. It is stressed that a high index of suspicion, the use of endoscopy and a liver biopsy are essential to avoid delay in diagnosis. The patients have a good prognosis provided that the diagnosis is established at an early stage and portacaval anastomosis performed.

CONGENITAL hepatic fibrosis was a term introduced by Kerr et al. (1961) to describe a condition occurring in children and young adults characterized by normal liver function, portal hypertension, hepatic fibrosis and preservation of the normal lobular liver architecture. Although the condition was first described by MacMahon in 1929, its clinical significance was not fully appreciated until recent years. Since the normal liver architecture and function are preserved the prognosis is good provided that the predominant clinical manifestation, portal hypertension, is treated adequately. This disease, however, is frequently diagnosed late and proper management is consequently delayed (Hermann and Hawk, 1967).

This paper presents 5 cases of congenital hepatic fibrosis which illustrate the difficulties in the clinical management. These patients, 3 of whom were personally managed, were encountered among 60 patients who underwent portasystemic shunt operations for the relief of portal hypertension during the years 1956–74 at the Glasgow Royal Infirmary.

Case reports

Case 1: A female child presented at the age of 1 year with haematemesis and melaena following ingestion of junior aspirin. There was no family history of haemorrhagic diathesis, congenital hepatic fibrosis or other hepatic pathology. On clinical examination the spleen and the liver were enlarged, but liver function tests were normal (*Table I*). Barium swallow studies showed no abnormality, and a diagnosis of Banti's syndrome was made. Liver biopsy was not performed. The patient was treated conservatively and discharged.

Three years later she again presented with haematemesis, and a barium swallow examination on this occasion showed oesophageal varices. She was treated by ligation of the splenic artery following which the spleen diminished considerably in size. Again liver biopsy was not performed and the diagnosis remained obscure.

Following this she remained well for a further 10 years, when she presented with iron deficiency anaemia, the haemoglobin being 11·1 g/100 ml. The packed cell volume was 37 per cent, white cell count 19 000/mm³ and platelets 248 000/mm³. The liver function tests were again normal and direct Coombs' test was negative. She was treated with oral iron therapy and discharged from hospital but without a firm diagnosis.

At the age of 17 the patient was admitted with massive haematemesis. She was treated by blood transfusion and intravenous vasopressin but without success. She continued to bleed, and direct transthoracic ligation of the gastro-oesophageal varices was carried out. Liver biopsy was performed at this time and a diagnosis of congenital hepatic fibrosis was made (*Fig*. 1). Intravenous pyelography revealed some fullness of the calices of the left kidney but no evidence of polycystic disease.

The patient had two further episodes of haematemesis in the following 2 years and another laparotomy was performed. The portal vein was found to be thrombosed and thrombectomy of the portal vein and a portacaval anastomosis was attempted.

Two years later she presented with a further gastro-intestinal haemorrhage. Oesophagogastroscopy demonstrated prominent varices in the oesophagus and the fundal region of the stomach. Liver function tests were again normal, the bilirubin being 0·8 mg/100 ml, SGOT 69·4 i.u./l, SGPT 21 i.u./l and alkaline phosphatase 6 KA units. At this point in her history she came under our care and a mesocaval shunt was carried out. The patient made an uneventful postoperative recovery and has been followed up for a year since the operation. Oesophagogastroscopy has been carried out at regular intervals and there has been diminution in the size of the varices. She remains well and has had no further bleeding. She has gained weight and is now working full time at a supermarket.

Case 2: This patient had a family history of congenital hepatic fibrosis and has been previously reported (Lorimer et al., 1967). She was remarkably healthy as a child but later in her life had multiple miscarriages. In 1964 at the age of 30 years she was admitted to hospital following an episode of haematemesis and melaena which was treated with blood transfusion and bed rest, but no definitive diagnosis was made. A year later she had two further episodes of gastro-intestinal bleeding, and more extensive investigations were undertaken. Clinically she appeared normal with no jaundice and no hepatosplenomegaly. A barium meal examination was carried out and oesophageal varices and a duodenal ulcer were demonstrated. Intravenous pyelography showed no abnormality. Liver function tests were within the normal range (*Table I*) and her bromsulphthalein excretion test showed 15 per cent retention at 30 minutes. Thrombotest was 45 per cent, direct Coombs' test was negative and serum copper oxidase and caeruloplasmin levels were also normal. The patient was slightly anaemic with a haemoglobin of 11·3 g/100 ml, packed cell volume of 32 per cent and platelet count of 50 000/mm³. Needle biopsy of the liver showed normal hepatic architecture intersected by a thick band of cellular fibrous tissue. At laparotomy the spleen was enlarged and the liver showed a 'fine cirrhosis'. The splenic pulp pressure was 36 cm H_2O and an operative portal venogram revealed a patent portal vein. Splenectomy and splenorenal anastomosis were carried out with a fall in the splenic pulp pressure to 24 cm H_2O. Liver biopsy obtained at operation showed the typical features of congenital hepatic fibrosis.

She remained well for 7 years following operation but was then readmitted with haematemesis. A duodenal ulcer was demonstrated on barium meal examination and a gastroenterostomy was therefore performed. She remained symptom-free for 2 years and was then admitted under our care with further haematemesis. She was not jaundiced but had definite

5	6·6	4·5	2·1	0·8	13·0	35	30

ascites. Liver function tests at this admission showed deterioration of hepatic function. The bromsulphthalein excretion test now showed retention of 50 per cent at 30 minutes, a bilirubin level of 1 mg/100 ml and alkaline phosphatase of 25 KA units. Oesophagogastroscopy showed prominent varices in the oesophagus and the cardiac region of the stomach. One of these varices was bleeding at the time of the endoscopic examination.

A mesocaval shunt was performed and the initial postoperative period was satisfactory. However, the patient then developed pulmonary oedema and bronchopneumonia. She became jaundiced and her condition progressively deteriorated. She died 19 days postoperatively. At post-mortem the liver was small and histology confirmed the diagnosis of congenital hepatic fibrosis. It also showed thrombosis of small hepatic venous radicles within the liver parenchyma. The mesocaval shunt was patent and the presence of bronchopneumonia was confirmed.

Case 3: This 60-year-old female patient was admitted with haematemesis. Oesophageal varices were demonstrated by barium swallow examination and a diagnosis of cirrhosis and portal hypertension was made. The liver function, however, was normal (*Table I*), the bilirubin being 0·8 mg/100 ml, SGOT 35 i.u./l, SGPT 30 i.u./l and alkaline phosphatase 13 KA units. Prothrombin time was also normal.

Splenoportography showed a patent portal vein and a portacaval anastomosis was performed. Biopsy of the liver was reported as showing atypical histological changes associated with cirrhosis of the liver, but the significance of the hepatic histology was not appreciated.

The patient was symptom-free for a year. She was readmitted with further haematemesis and was treated conservatively. A year later she presented again with gastro-intestinal haemorrhage and was managed by sedation, blood transfusion and intravenous administration of vasopressin. The haemorrhage, however, continued unabated and a Sengstaken tube was placed in the oesophagus. The patient's condition progressively deteriorated and she was transferred to our care.

The patient was semi-comatose, having had 12 units of blood transfused. A coagulation screen revealed an extrinsic clotting defect and thrombocytopenia, the platelets being 70 000/mm³ The liver function tests showed normal values of serum proteins, alkaline phosphatase and transaminases but the bilirubin was 10 mg/100 ml.

Splenoportography demonstrated an intact and patent porta vein, and there was no radiological evidence of portacaval shunt which was alleged to have been performed at a previous admission. Laparotomy was carried out and dense adhesions precluded dissection of the porta hepatis. Splenectomy and splenorenal shunt were performed and the liver biopsy confirmed the diagnosis of congenital hepatic fibrosis. Post operatively the patient developed hypotension, acute lef ventricular failure and anuria, and died 24 hours after operation. The post-mortem examination showed an intac splenorenal anastomosis but again no evidence of the portacaval shunt operation allegedly performed 2 years previously.

Case 4: A young boy aged 11 presented with haematemesis One year later he had a further attack and was noted to have hepatomegaly, but liver function tests were normal. Three year later he had a further episode of haematemesis and again live function tests were normal. During this admission his liver and spleen were both palpable. In view of the recurrent episodes o haemorrhage, splenectomy and splenorenal anastomosis were carried out. No liver biopsy was, however, performed.

The following year he had a further haematemesis and developed deep vein thrombosis. This presentation wa repeated 2 years later. He had three further episodes of haematemesis over the following 3 years and at that time, at the ag of 22, a further laparotomy was undertaken. The portal vei was found to be thrombosed and no definite operative procedure was undertaken. A liver biopsy demonstrated congenita hepatic fibrosis.

Four years later at the age of 26 he was readmitted, havin had five episodes of haematemesis and melaena. Liver functio tests were again normal (*Table I*). An oesophagogastrectom was performed but the patient collapsed and died on the second postoperative day.

Case 5: This male patient enjoyed good health until 1969 when, at the age of 29 years, he was admitted to hospital with haematemesis. Examination showed hepatosplenomegaly but the liver function tests were normal. His haemoglobin was 14·4 g/100 ml and platelets 36 000/mm^3. There was no family history of congenital hepatic fibrosis. He was submitted to laparotomy and the portal pressure was recorded as 32 cm H_2O. Splenectomy and a splenorenal anastomosis were carried out, and a diagnosis of congenital hepatic fibrosis was made on liver biopsy. His postoperative liver function tests showed little change from the preoperative findings. He has remained symptom-free since his operation and is now an active member of a parachute regiment.

Discussion

The aetiology of congenital hepatic fibrosis is not fully established but there is evidence that the condition is due to maldevelopment of the intrahepatic biliary system (Melnick, 1955). Familial incidence has been described (Lorimer et al., 1967; Campbell et al., 1958), and an autosomal recessive gene was incriminated by Kerr et al. (1961). The histological features are now well recognized (Nathan and Batsakis, 1969; Sommerchild et al., 1973): the lobular architecture of the liver is preserved but there is an increase in fibrous tissue and biliary ducts in the interlobular stroma (*Fig.* 1). Bile ducts may also be more numerous in otherwise normal portal tracts (Lorimer et al., 1967).

It is important that the correct diagnosis be established at an early date so that appropriate treatment can be instituted. These patients usually present with gastro-intestinal bleeding from oesophageal varices and have normal liver function, in contrast to patients with cirrhosis. The liver may be enlarged and splenomegaly is frequent. Splenoportography shows portal hypertension and a patent portal vein, suggesting an intrahepatic rather than an extrahepatic cause for the portal hypertension. Cystic anomaly of the kidneys demonstrated by intravenous pyelography adds further weight to the diagnosis of congenital hepatic fibrosis. Renal function, however, is usually normal. Percutaneous liver biopsy may be difficult to perform owing to the hard consistency of the liver, but biopsy with a Trucut needle (Travenol Laboratories Inc., Illinois, USA) provides connective tissue as well as parenchymal evidence and usually gives an adequate core, allowing accurate histological examination.

The prognosis is good provided that portal hypertension is corrected early in the course of the illness. However, owing to failure to perform a liver biopsy the diagnosis is often delayed, and as a result the patients undergo multiple inadequate operative procedures. This pattern is well illustrated by 3 of the cases described here (*Cases* 1, 2 and 4). The patients were treated at various hospitals for a number of years before liver biopsy gave the diagnosis and definitive portal decompression could be carried out.

The normal liver function and a patent portal vein make these patients excellent candidates for a portasystemic shunt with little risk of encephalopathy. The ideal operation is end-to-side portacaval anastomosis, but in very young children the procedure may be difficult. However, successful portacaval shunts can be performed after the age of 6 years (Hermann and Hawk, 1967). It has been recommended that an elective portasystemic shunt be performed in symptom-free patients with established portal hypertension due to congenital hepatic fibrosis (Sommerchild et al., 1973), and we would endorse this view. It is preferable to avoid splenectomy unless combined with splenorenal shunt as this may lead to thrombosis of the splenic or even the portal vein and so make further surgery difficult. This is well illustrated in *Cases* 1 and 4.

It is to be emphasized that these patients have a good chance of a normal lifespan if correct treatment is instituted at an early stage. A high index of suspicion, especially in young children or adolescents with haematemesis, the use of endoscopy in defining the site of haemorrhage, liver biopsy and adequate portasystemic shunt operation at the earliest opportunity are essential principles in the management of these patients. Our experience, like that of Kerr et al. (1961), indicates that the best results can be expected from early portacaval anastomosis.

Splenic-gonadal fusion

A. K. PENDSE, P. N. MATHUR, M. M. SHARMA AND O. P. GUPTA*

SUMMARY

Various aspects of splenic-gonadal fusion are discussed and 1 case of the continuous type is reported. A plea is made to include this condition in the differential diagnosis of scrotal masses, particularly those on the left side.

SPLENIC-GONADAL fusion, manifesting as abnormal connections between the spleen and the left gonad or the derivatives of the left mesonephros, has been observed occasionally. Fifty-four cases of this anomaly had been reported up to 1969 (Mendez and Morrow, 1969). These masses, which invariably occur on the left side, are often taken to represent a third testicle or a testicular tumour. A case of splenic-gonadal fusion is presented and important aspects of this condition are reviewed in this paper.

Case report

G. C., aged 2½ years, was admitted with a history of left-sided scrotal swelling which had first been noticed by the parents about 6 months previously. The swelling tended to vary in size.

On examination a 5 × 3 cm swelling was palpable in the left scrotum. It was firm in consistency, and the testis and epididymis could not be palpated separately. The cord was slightly thickened. Trans-illumination was negative.

The left scrotum was explored under general anaesthesia. There was a congenital hernial sac with an unobliterated processus. The testis and the epididymis were elongated and did not show a normal configuration. On the lateral aspect of the testis and epididymis there was a 5 × 3-cm oblong mass with a broad lower end adjoining the globus major and tapering towards the upper end. From the tapering end and also from the testis a fibrous cord extended along the spermatic cord and disappeared beyond the internal inguinal ring. The mass was reddish-brown in colour and had a glistening capsule. It could not be dissected away from the testis and the epididymis. Because of this and the uncertainty about the nature of the mass, orchidectomy was carried out. The postoperative course of the patient was uneventful.

Gross examination confirmed the operative findings (*Figs.* 1, 2). Histological examination revealed histologically normal splenic, testicular and epididymal structures with a fibrous septum separating the two elements.

Discussion

Classification

There are two forms of the malformation:

1. *Continuous splenic-gonadal fusion* in which the spleen remains connected with the left gonad by a continuous strand of splenic tissue or by a fibrous cord containing accessory splenic islands at various levels. The cord usually arises from the upper pole of the spleen (Putschar and Manion, 1956), although it may arise from the hilum (Bennett-Jones and St. Hill, 1952) or from the lower pole (Daniel, 1957). The spleen is otherwise normally formed and located, but may be lobulated or fissured. The cord tapers from the

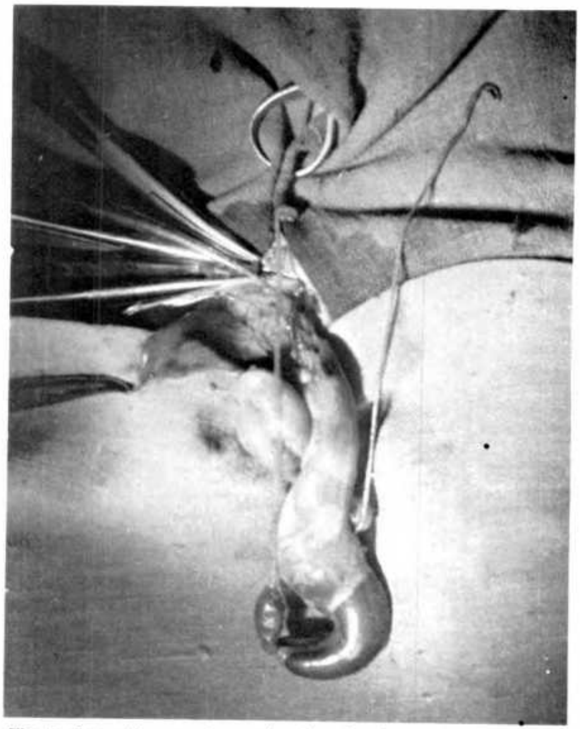

Fig. 1. Operation specimen showing the elongated testis and epididymis (upper pale structure) and curved tapering splenic tissue (lower dark structure). The two fibrous cords are also visible.

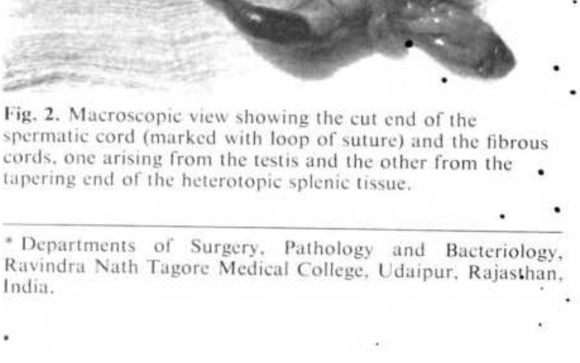

Fig. 2. Macroscopic view showing the cut end of the spermatic cord (marked with loop of suture) and the fibrous cords, one arising from the testis and the other from the tapering end of the heterotopic splenic tissue.

spleen downwards, or is beaded with local aggregations of the splenic tissue, and often ends in a bulbous mass of spleen attached to the gonad (Willis, 1962). The cord traverses the peritoneal cavity as a free structure in front of the intestines, but may be paracolic.

2. *Discontinuous splenic-gonadal fusion* in which a mass of accessory splenic tissue is attached to the gonad, but there is no connecting cord between this and the spleen proper. The accessory paragonadal spleen is usually a distinct encapsulated mass attached to the testis or to the head of the epididymis. Occasionally there may be multiple masses.

Aetiology

Between the fifth and eighth embryonic weeks the developing splenic rudiment in the dorsal mesogastrium is in close relationship to the mesonephros and gonadal rudiment. Abnormal adhesion of the two rudiments, as most investigators assume (Putschar and Manion, 1956), or the development of splenic tissue from a wider field than normal, extending on to the dorsal coelomic wall (Willis, 1962), would account for caudal displacement of the part of the spleen in contact with the gonad when the latter descends. This explains the genesis of the continuous type of splenic-gonadal fusion. The less frequent discontinuous type of fusion may be derived from an isolated hump of the splenic anlage, or the original connection with the main spleen may disappear, leaving no vestiges.

Associated malformations

These have been present in approximately 20 per cent of the recorded cases and include peromelus, micrognathia, atresia of the anus, asymmetry of the skull and abnormal fissures of the lung and liver. Putschar and Manion (1956) point out the too frequent association of peromelus and micrognathia with splenic-gonadal fusion and suggest that these features may constitute a syndrome. The associated malformations have been reported exclusively in the continuous type of fusion. None of the reported discontinuous types showed any such malformations.

Gross and histological findings

The splenic tissue is only in close approximation with the gonad and usually no intermingling with the mesonephric-gonadal tissue is seen, though this has occasionally been reported (Bennett-Jones and St. Hill, 1952).

The splenic tissue of the cord as well as of the isolated aberrant spleen is histologically normal, but may show regressive changes such as fibrosis, thrombosis, calcification, thickening of the trabeculae and deposition of blood pigment. The splenic tissue may participate in the function of the main spleen and show hyperplasia (Emmett and Dreyfuss, 1943). It is also subject to the same pathological conditions as the main spleen.

The area of fusion with the gonad is variously described as a thinned or thickened layer of fibrous tissue. The gonad is usually normal histologically but may show atrophy, fibrosis and an increased number of Leydig cells (Talmann, 1926; Tate and Goforth, 1949).

Clinical considerations

The sex distribution of this congenital anomaly strongly favours the male, especially in the continuous type of fusion.

The left gonad is almost exclusively involved; only 1 case of right scrotal spleen has been reported.

The aberrant splenic tissue is usually found accidentally during hernial repair, operation for undescended testicle or at necropsy. The splenic tissue may present as a scrotal mass or masses and is then taken to represent a third testicle (Daniel, 1957) or is confused with a testicular tumour (Horovitz and Griffel, 1959; Mendez and Morrow, 1969). Pain and tenderness, particularly during strenuous exercise, may force the patient to seek medical advice. Enlargement of the mass during systemic infections and malaria has also been reported. Accessory splenic tissue must be considered in the differential diagnosis of scrotal masses, especially on the left side.

The abnormal fusion of the spleen to the mesonephric-gonadal structures frequently interferes with the normal completion of gonadal descent and the orderly closure of the processus vaginalis. Of the 54 reported cases, 17 had an associated inguinal hernia and 9 had incomplete gonadal descent (Mendez and Morrow, 1969).

Splenic-gonadal fusion *per se* does not require any treatment. The heterotopic splenic tissue is usually revealed during exploration of a scrotal mass and, unless one is aware of this anomaly, orchidectomy is carried out, as was done in our case. Repeated attacks of pain and swelling, specially in the presence of an atrophic testicle, necessitate orchidectomy. Excision of the heterotopic splenic tissue is indicated when it participates in diseases involving the spleen (leukaemia, infectious mononucleosis, etc.), or when its continued presence results in failure of splenectomy in cases of thrombocytopenic purpura and acholuric jaundice. The splenic-fibrous band stretching from the spleen to the internal inguinal ring may cause mechanical intestinal obstruction (Hines and Eggum, 1961).

Appendix: Review of reported cases

Fifty-four cases of splenic-gonadal fusion have been reported in the literature. The details of clinical presentation and gross and microscopic features are available for 37 of the cases and are given in *Table I*. A review of the reported cases shows a marked preponderance of males—50 males and 4 females. The continuous type of splenic-gonadal fusion (type I) was present in 25 cases, the discontinuous type (type II) in 23 cases while the type was not specified in 6 cases. Inguinal hernia was reported to be present in 18 cases, absent in 20 cases and was not specifically mentioned in 16 cases. Incomplete descent of the fused gonadal-splenic structure was present in 9 cases,

Table I: DETAILS OF THE REPORTED CASES

Authors	Sex (age, yr)*	Clinical diagnosis	Type (side)†	Gross anatomy	Histology/Associated anomalies‡
1	M (n.g.)	No details	I (l.)	Fusion, with normal location of both organs	No details
2	M (n.b.)	No details	I (l.)	Cord 5·5 cm long, 3·5–6 mm wide. Testes undescended	No details *Perobrachius apus, micrognathia, anal atresia and defect of coccyx*
3	M (n.g.)	No details	I (l.)	No details	No details *Not mentioned*
4	M (a.)	Third testicle	I (l.)	Nodule 2 × 1 cm. Cord 33·4 cm long, 1–10 mm wide	Histologically normal spleen *Not mentioned*
5	M (25)	Inguinal hernia	I (l.)	Nodule 2·5 cm. Cord 43 cm long	Histologically normal spleen *Not mentioned*
6	M (10)	Death due to typhoid	I (l.)	Both testicles at external ring	Hypoplastic testes *Absence of left lower leg*
7	M (n.b.)	Inguinal hernia	II (l.)	Spleen in left epididymis	No details *Not mentioned*
8	M (22)	Tenderness and swelling of the left testicle after long marches and during malaria	II (l.)	Mass 2·5 cm in the head of the epididymis and another on the spermatic cord	Atrophic testicle, splenic hyperplasia *Not mentioned*
9	M (19)	Exploration at age of 12 for scrotal mass	II (l.)	Three masses at the lower pole of testis	Atrophic changes in the testis. Normal splenic tissue *Not mentioned*
10	F (n.b.)	No details	I (l.)	Cord 77 mm long, 0·5–2·5 mm wide	No details *Not mentioned*
11	M (11)	Found during operation for undescended testicle	I (l.)	Cord 2 mm wide	Histologically normal spleen *Not mentioned*
12	M (n.g.)	Tertian malaria with painful swelling of the scrotal spleen	II (l.)	No details	No details *Not mentioned*
13	M (30)	Exploration at age of 12 for scrotal mass	II (l.)	Three masses at the lower pole of testis	Atrophic changes in the testicle, normal spleen *Not mentioned*
14	M (19)	Congenital left inguinal hernia with aberrant spleen	I (l.)	Pear-shaped mass 4·6 × 2·2 × 1·5 cm. Cord 9 cm long	Histologically normal spleen *Not mentioned*
15	M (43)	Bilateral inguinal hernia with tumour of left testicle	II (l.)	Mass 4 × 2 cm at the upper pole of testis	Histologically normal splenic and testicular tissue *Not mentioned*
16	M (45)	Cause of death: peritonitis from perforated bleeding duodenal ulcer	I (l.)	Spleen 200 g, normal position. Cord 0·3–0·5 cm wide. Ectopic spleen 1·8 × 1 × 1 cm as bulbous mass at head of epididymis	Splenic tissue with inflammatory hyperplasia *Not mentioned*
17	M (32)	Pain in left testicle and scrotum. Mass noticed since birth. Discomfort after exercise	I (l.)	Marble-sized splenic tissue at lower end of left spermatic cord. Cord 12 cm long followed only up to internal ring	Normal splenic tissue *Not mentioned*
18	M (9)	Found during medical inspection at school	II (l.)	Walnut-sized accessory spleen at inferior pole of testicle	Histologically normal spleen *Not mentioned*
19	M (21)	Swelling noticed at age of 13, after operation for undescended testicle	I (l.)	Mass 7 × 4 × 4 cm attached to atrophic left testicle. Tail-like process along spermatic cord, 10 cm long, followed up to inguinal ring	Normal splenic tissue. Atrophic testis without spermatogenesis, increased fibrous tissue and Leydig's cells *Not mentioned*
20	M (9)	On palpation of heavy right testicle, five times normal size with irregular bosselated surface. Diagnosis: malignant tumour	II (r.)	Specimen showed semi-lunar-shaped testicle in upper third and firm, reddish nodular splenic mass in lower two-thirds	Normal spleen and immature testis *Not mentioned*
21	M (4)	Noted at physical examination for cardiac malformation	II (l.)	Accessory spleen 3 × 5 × 2 cm in upper pole of left testicle	Histologically normal spleen and testicle *Patent ductus arteriosus*
22	M (69)	Cause of death: fall from tree, rupture of aorta and mediastinal haemorrhage	I (l.)	Bilobed spleen with a beaded cord from lower pole to 2-cm splenic mass in upper pole of left testis	Normal spleen with considerable free pigment *Not mentioned*
23	M (13)	Left testicle larger than right since birth, painful on effort—malignant tumour	II (l.)	Splenic mass 8 × 4 × 3 cm at upper pole of left testis	Spleen with hyalinization of arterioles *Not mentioned*
24	M (10)	Seen at 7 years because of tender enlarged testis. Diagnosis: partial torsion or thrombosis of spermatic cord	I (l.)	Cord 20 cm long, 0·6–1·2 cm wide. Little macroscopic demarcation between cord and splenic mass	Histologically normal spleen *Not mentioned*

25	F (n.b. probably)	No details	I (l.)	Splenic cord from upper pole of left spleen to slightly undescended left ovary. Two intra-ovarian splenic nodules	No details *Thoracopagus, single jejunum and ileum, Meckel's diverticulum and vascular anomalies*
26	M (6/12)	Cause of death: bronchopneumonia	I (l.)	Medium-sized spleen 5 cm. Splenic process from upper pole continuing as 7-cm long fibrous cord inserted at left innominate line. Both normal testicles in scrotum	No details *Peromelus, micrognathia, absence of both forearms and legs, abnormal fissures of lungs and liver, asymmetry of skull*
27	F (s.b.)		I (l.)	Spleen 6 × 2·3 cm, normal position. Elongated process from upper pole, 0·5 cm wide at lower end, attached to partly undescended left adnexa. Tubes, ovaries and uterus normal	Normal congested splenic tissue. Splenic cyst with capsule-like wall *Micrognathia, absence of both forearms and hands, absence of right lower leg and foot*
28	M (24)	Recurrent attacks of epididymitis and inflammation of spermatic cord following herniorrhaphy several years previously	II (l.)	Accessory spleen 4·5 × 2 × 1 cm with smooth grey capsule, located in upper part of left testicle	Splenic tissue with some fibrosis of stroma and reduced pulp *Not mentioned*
29	M (23)	Mass in scrotum since 1945. Recent increase in size, without symptoms	II (l.)	Accessory spleen 1·7 × 2·3 cm in upper pole of left testis, completely encapsulated testis; epididymis and vas normal. Dilatation of pampiniform plexus	Histologically normal splenic tissue *Not mentioned*
30	M (11)	Tumour of scrotum	II (l.)	Mass 1·5 × 1·4 × 1·1 cm, encapsulated, ovoid, smooth, deep red surface; cut surface greyish-pink in soft tissue between scrotal skin and spermatic cord	Well-defined capsule with many lymphoid follicles, elongated sinusoidal spaces lined by endothelium *Not mentioned*
31	M (44)	Pain and swelling in lump in left scrotum for 15 mth. Lump noticed at age of 8. Exploration at 21 yr	I (l.)	Small nodule of splenic tissue, red-brown in colour, in upper pole of left testis, but separate from it. Cord not traced but palpable clinically up to external ring	Histologically normal spleen *Not mentioned*
32	M (26)	Soreness and pain in third testicle, noticed since birth, and left inguinal hernia. Congenital tumour or duplication of left testis	I (l.)	Two masses, 2·3 × 3·5 cm, firm, solid, homogeneous brownish red, each with a cord 27 cm long, average diameter 0·75 cm	Normal spleen and testicle *Not mentioned*
33	M (5)	Soft, non-tender swelling in left scrotum, moving with testicle. Clinical diagnosis: hydrocele	II (l.)	Dark brown, well-encapsulated tumour 2·5 × 2 × 2 cm	Normal spleen and testicle *Not mentioned*
34	M (15)	Acute intestinal obstruction due to elongated projection of splenic tissue	I (l.)	Elongated projection of splenic tissue extending from lower end of bilobate spleen. Lower end fibrous, leaving abdomen through left inguinal ring. Testicular connection not traced	Not mentioned *Not mentioned*
35	M (32)	Swelling of left side of scrotum since childhood. Gradual increase in size, no pain. Clinical diagnosis: neoplasm of testis	II (l.)	Mass of tumour and testes 12 × 8 × 7 cm. Testis compressed at the lower pole of the tumour. Encapsulated, reddish brown splenic tissue	Congestive splenomegaly. Little atrophy of the compressed tubules with absent spermatogenesis in testis *Not mentioned*
36	F (48)	Nullipara with menorrhagia and double uterus	I (l.)	Mass 1·5 cm attached to left ovary	Not mentioned *Double uterus*
37	M (49)	Clinical diagnosis: epididymo-orchitis with embarrassed testicular blood supply. Hernioplasty on same side	II (l.)	Mass 10 × 8 × 7 cm, bright red. No evidence of testicular tissue, but with a dilated 3·5 × 4 cm cystic cavity	Fibrocongestive splenomegaly; dense fibrous connective and inflammatory tissue with abscess formation and foreign body granuloma *Not mentioned*

‡ Associated anomalies shown in italics.

absent in 36 cases, and was not specified in 9 cases. In all of the reported cases except one the anomaly affected the left gonad.

A correct preoperative diagnosis of scrotal spleen was made in only 1 of the 54 cases. Most of the cases were discovered at clinical examination for some other disease or during exploration for inguinal hernia or undescended gonads. The mass has often been confused with a scrotal/testicular neoplasm, a supernumerary testis or epididymo-orchitis. In 1 case the splenic-fibrous cord caused acute intestinal obstruction. The heterotopic splenic tissue has been reported to manifest changes similar to those occurring in the parent spleen.

Abdominoscrotal hydrocele

B. R. PAREKH, G. REINBOTH AND O. P. MISHRA*

SUMMARY

The number of cases of abdominoscrotal hydrocele reported in the literature has been brought up to date, which, including the 3 cases reported here, is 83 of which 21 are from India.

The pathogenesis of this lesion is discussed. It is concluded that all cases of abdominoscrotal hydrocele are due to progressive involvement and distension of the patent processus vaginalis which is cut off from the general peritoneal cavity.

A new classification of abdominoscrotal hydrocele is suggested on the basis of experience gained from the 3 cases reported here.

SINCE the first description by Dupuytren in 1834, who called this condition 'l' hydrocèle en bissac', numerous names have been suggested from time to time. Lister, who was interested by the extraordinary clinical appearance of a patient, did a post-mortem dissection of this lesion and published his results in 1856. Jacobson, whose classification of the types of hydrocele is still used today, described it as 'infantile hydrocele with prolongation into the abdomen' in his textbook published in 1893. However, it was Bickle in 1919 who suggested the term 'abdominoscrotal hydrocele' for this condition as a proper descriptive title, and although Holmes recommended the term 'properitoneal hydrocele' in 1932, the term 'abdominoscrotal hydrocele' is now generally used.

Abdominoscrotal hydrocele is considered a relatively rare condition, and most of the published reports are based on a single case. To the best of our knowledge the total number of cases reported in the literature to date is 80. These include 18 cases reported from India during the past 10 years, The present report is based on the experience of 3 cases, all young male Hindus, which bring the total of published cases to 83 including 21 from India.

Case reports

Case 1: M. L. M., aged 30 years, was admitted on 5 May 1959 with a gradually increasing swelling in the right side of the scrotum of 2 years' duration. The past history and family history were non-contributory. General and systemic examinations found nothing significant. Local examination revealed a right-sided, moderately large and tense, inguinoscrotal, cystic, translucent swelling in which a cough impulse was present. A clinical diagnosis of right-sided infantile hydrocele was made.

The patient underwent operation on 6 May (O. P. M.). Through an inguinal incision the distended processus vaginalis lying in the inguinal canal was dissected free from the spermatic cord and tapped to reduce the size of the scrotal part of the hydrocele, and then the scrotal part of the hydrocele with the testis was delivered into the inguinal canal. It was noted with surprise that the amount of straw-coloured hydrocele fluid collected in the suction bottle was obviously much more than what appeared to have been contained in the hydrocele sac. The sac was opened and a finger passed into the proximal part of the sac and negotiated through the internal inguinal ring where the lumen of the processus vaginalis was expected to be obliterated. However, a finger slipped in as it would in a hernial sac, but the loops of the intestine could not be felt in direct contact with finger. It was then realized that the condition was an abdominoscrotal hydrocele and the abdominal part of the hydrocele sac was lying in the properitoneal space deep to the fascia transversalis. With gentle and steady traction the whole of the abdominal part of the sac was pulled out through the internal ring. At this stage the obliterated communicating isthmus between the processus vaginalis and the peritoneal cavity came into clear view (*Fig.* 1). With gentle manipulation, a closed artery forceps was made to pass through this isthmus which was then stretched and a finger inserted into it. This finger came into direct contact with a loop of intestine. The isthmus was transfixed and divided and the proximal sac was excised by dividing the processus at the upper pole of the testis. The tunica vaginalis was everted and the testis returned into the scrotum. The incision was closed in layers.

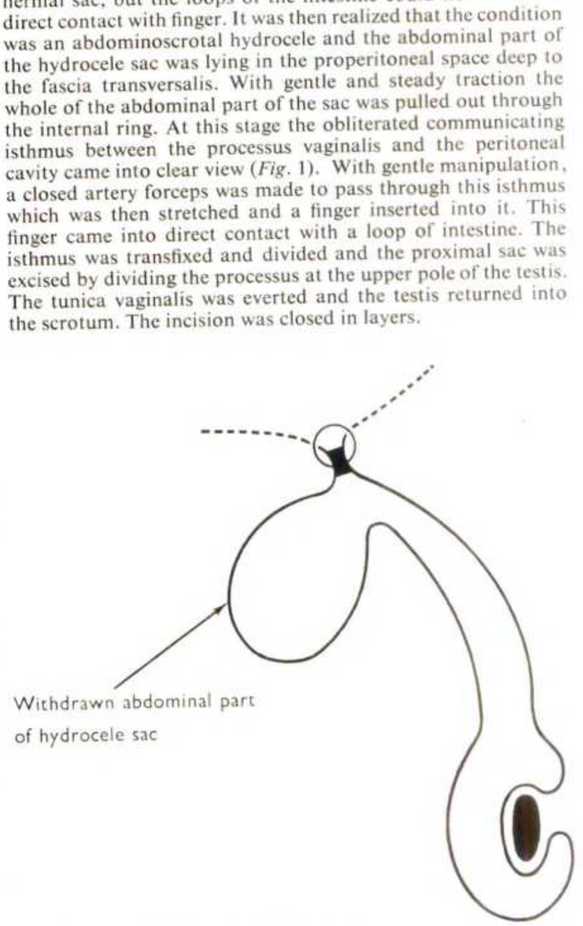

Fig. 1. *Case* 1. Diagram of the hydrocele.

Case 2: J. K. N., aged 20 years, presented on 17 February 1969, with a painful irreducible swelling in the right inguinal region. The patient had noticed a small swelling in this region about 1 month previously which was neither painful nor tender. He could not confirm or deny the reducibility of the swelling. The swelling had suddenly became painful about 20 hours before admission. The patient gave no history of distension of the abdomen and had passed a normal motion in the morning. General and systemic examinations revealed no abnormality. Locally, there was a swelling about 2·5 cm in diameter. The skin over the swelling was normal and moved freely. The swelling was cystic, tender and irreducible. A clinical diagnosis of strangulated omentocele was made and an emergency operation under spinal anaesthesia was performed (O. P. M.).

Fig. 2. *Case* 2. Diagram of the hydrocele.

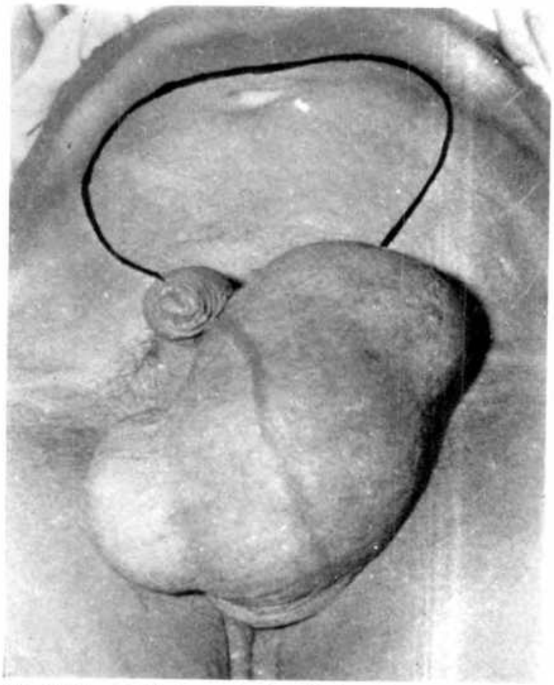

Fig. 3. *Case* 3. Photograph of the hydrocele. The cystic swelling in the abdomen is outlined.

Through an inguinal incision a thin-walled, tense, cystic swelling measuring 5 × 2·5 cm and containing clear straw-coloured fluid was seen lying in the inguinal canal and extending up to the internal inguinal ring; the appearances were of a high encysted hydrocele of the cord. There appeared to be no cause to explain the sudden pain and tenderness in the swelling, and hence it was presumed to be due to partial volvulus which had already been relieved either spontaneously or during the exposure and handling of the swelling. An attempt was made to separate the sac from the structures of the cord for excision, but during the dissection the cyst ruptured. At the extreme proximal end of the cyst a narrow processus communicating with the lumen of the cyst was found entering the internal inguinal ring. With gentle and steady traction the processus was pulled out, and was found to have dilated into a larger sac lying in the properitoneal space. The whole of the properitoneal part of the sac was easily brought out. This sac was attached to the parietal peritoneum by a narrow obliterated isthmus of the processus vaginalis (*Fig.* 2). As in *Case* 1, with gentle manipulation a closed artery forceps was made to pass through the isthmus in order to confirm the communication with the general peritoneal cavity, and then the isthmus was transfixed and the hydrocele sac was excised. The patient had an uneventful recovery and was discharged from hospital on 26 February.

Case 3: K. S., aged 25 years, was admitted on 13 April 1973 with a swelling in the left scrotum which had been gradually enlarging for the past 6 months. The past history and family history were non-contributory. No abnormality was detected on general and systemic examination. On local examination there was a moderately large, translucent, left-sided, vaginal hydrocele. A visible cough impulse was present. On further examination a fairly large cystic swelling was found in the abdomen, occupying the hypogastric region and part of the left lower abdomen and extending upwards beyond the umbilicus (*Fig.* 3). This swelling was dull on percussion and was non-tender, and the patient was unaware of its presence. The swelling became less prominent on contraction of the abdominal muscles, and was felt per rectum on being pressed down by a hand placed on the abdomen. Cross-fluctuation was present between the abdominal and scrotal swellings. A clinical diagnosis of abdominoscrotal hydrocele was made and the patient underwent operation on 28 April under spinal anaesthesia (O. P. M.).

The scrotal part of the hydrocele was exposed through a 6-cm scrotal incision placed 1 cm to the left and parallel to the median raphe. The sac was tapped through a wide bore needle connected to a suction machine in order to reduce its size, and the structures of the spermatic cord were separated from the sac at the upper part of the scrotum. Then, with gentle and

steady traction and blunt finger dissection with a piece of gauze, the whole abdominal part of the hydrocele sac was pulled out. The larger part of the abdominoscrotal sac was excised and the remaining smaller tunica vaginal part everted. The scrotal incision was closed after leaving a rubber drainage tube in the scrotum. The patient developed a small haematoma in the lower abdomen which gradually subsided, and he was discharged from hospital on 17 May, i.e. 19 days after the operation.

Discussion

Incidence

Although since its first description in 1834 only 62 cases of abdominoscrotal hydrocele had been collected from the literature up to 1964, during the past 10 years 21 cases have been reported, all from India. It is probable that many cases have remained unreported in the past.

Aetiology

Dupuytren (1834) suggested that a vaginal hydrocele may, on increasing distension, push its way up through the inguinal canal and assume an abdominal position. Kocher (1878, 1887), Currie (1953) and Burkitt and Williams (1964) shared this view. However, it appears unlikely that a vaginal hydrocele, instead of distending the scrotum, would on enlarging enter the external inguinal opening and then the inguinal canal to find its way into the properitoneal space through the internal inguinal ring. We believe that it would be possible only if an increasing vaginal hydrocele opens up a partially obliterated processus vaginalis from below upwards to a point where the processus vaginalis is firmly obliterated.

It is generally believed that in abdominoscrotal hydrocele the scrotal swelling usually precedes the onset of the abdominal one (Mitra et al., 1972). *Case* 2 in the present report is therefore of special interest. This patient had an abdomino-inguinal hydrocele. It seems that the initial lesion was an encysted type of the hydrocele of the cord situated in the proximal part of the inguinal canal reaching the internal ring. The proximal end, on distending, invaginated the internal ring and formed the properitoneal abdominal part of the hydrocele sac.

We suggest that abdominoscrotal hydroceles should be classified as follows:

1. Complete abdominoscrotal hydrocele (*Fig.* 4).
   - *a.* Indirect type (*Fig.* 4*a*).
   - *b.* Direct type (*Fig.* 4*b*).
2. Incomplete abdominoscrotal hydrocele (*Fig.* 5).
   - *a.* Abdomino-inguinal hydrocele.
     - i. Indirect type (*Fig.* 5*a*).
     - ii. Direct type (*Fig.* 5*b*).
   - *b.* Inguinoscrotal hydrocele (*Fig.* 5*c*).

Excision

It is now generally accepted that excision of the abdominal part of the sac and eversion of the tunica vaginalis is the treatment of choice. Many incisions have been advocated to achieve this. We now believe that a conventional inguinal incision with the technique employed by Lord (1959) in the direct type, and the technique used by us in the indirect type of abdominoscrotal hydrocele will serve the need adequately. Reduction of the size of the hydrocele after exposure, by aspiration or tapping, makes the incision easy, and a postoperative pressure bandage for 48 hours prevents large haematoma formation.

When pseudomonas threatens...

Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . and infection can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Triorchidism with normal spermatogenesis: an unusual cause for failure of vasectomy

M. HAKAMI AND S. H. MOSAVY*

SUMMARY

The wife of a vasectomized man became pregnant by her husband. He was examined and a supernumerary testis with intact vas and with normal histology and normal spermatogenesis were discovered.

TRIORCHIDISM is a rare anatomical entity. Wescott and Dykhuizen (1967) adequately described the embryological development of supernumerary testes. Twenty-four cases have been reported previously, and only 5 patients in addition to the one presented here have shown spermatogenesis (Jichlinski and Ward-McQuaid, 1963; Corwin et al., 1970; Smart, 1972).

Case report

The patient, aged 45 years and father of 4 children, was first referred to us because, in spite of bilateral vasectomy 2 months before, his wife had developed amenorrhea of 4 months' duration. Semen analysis had not been performed following vasectomy. On examination the patient appeared normal except that two lumps were detected in the right hemiscrotum which felt like small testes and did not permit transillumination. Both had firm cord-like structures palpable up to the external inguinal ring. The left testis was normal. Laboratory investigations including excretory urography were normal. Semen analysis revealed normal spermatogenesis. On examination his wife was thought to be pregnant, compatible with 4 months' duration of amenorrhea.

A presumptive diagnosis of triorchidism was made, and at operation, under local anaesthesia, two vasa deferentia were detected in the right scrotum and were exposed throughout their length, during which it became evident that one of them had previously been partly resected. A further 1-cm length of the upper end of this vas deferens was excised. The second vas deferens on the same side was seen to be intact and measured 4 cm. At no point did the two structures communicate. A 2-cm length of this supernumerary vas deferens was resected. Both right hemiscrotal testes were biopsied and showed normal histology. In addition, the testis with the intact vas deferens showed normal spermatogenesis (*Fig.* 1). On the left side a partly resected vas deferens was present. A second resection was performed on the upper end. Histological examination of the three resected vasa deferentia established their nature so that triorchidism with normal spermatogenesis was confirmed. The problem was explained to the patient and his wife.

Discussion

The first histologically proved case of polyorchidism was reported by Lane in 1895. Since then sporadic cases have appeared in the literature (Boggon, 1933; Jichlinski and Ward-McQuaid, 1963; Wescott and Dykhuizen, 1967). The condition may be associated with other congenital abnormalities including anomalous union between the testis and its epididymis, fixation of the epididymis to the testicle in its unusual anatomical position, absence of a rete testis and/or absence of all epididymal appendage, hernia and hydrocele (Corwin et al., 1970).

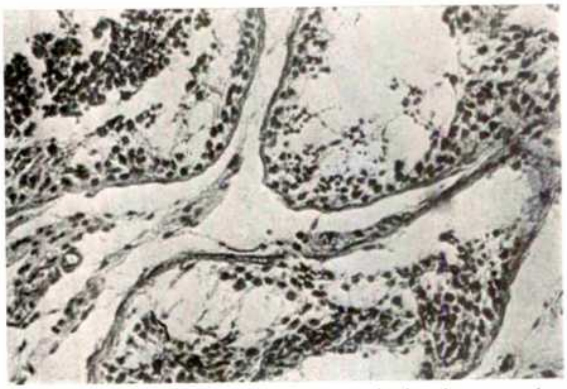

Fig. 1. Section of the supernumerary testis showing normal spermatogenesis.

This report emphasizes the need for a thorough urogenital examination before vasectomy and a further, if unusual, justification for the performance of routine postvasectomy semen analysis.

Immediate operative fitting of upper limb prosthesis at the time of amputation

K. P. ROBINSON, B. G. ANDREWS AND M. VITALI*

SUMMARY

Three patients are described—2 with an above-elbow amputation and 1 with a through-wrist amputation—in whom a temporary prosthesis was applied on the operating table and in all of whom function was rapidly established. The patients did not become one-handed, with the result that they have all continued to wear their prosthesis throughout their working hours and use their artificial hand for all everyday functions. The value of this technique in making the patient accept the prosthesis and therefore to make full use of it suggests that this procedure should be more widely applied in patients who require upper limb amputation.

AMPUTATION of the upper limb is less frequently performed than lower limb amputation, but on the occasions when the operation is performed the patient concerned is usually of a younger age group and the loss of part of an upper limb represents a more extreme disability, particularly when the sophisticated function of the human upper limb is considered. Many patients who have an upper limb amputation prefer not to wear an artificial limb and therefore do not obtain any benefit from a prosthesis. One reason for this is that once all or part of an upper limb is amputated the patient quickly learns to compensate the loss by the use of the remaining normal upper extremity, often to such good effect that the apparently cumbersome prosthesis is never accepted and frequently abandoned.

To prevent this rejection of an upper limb prosthesis it is felt that the immediate fitting on the operating table maintains a complete body image and cerebral representation of the missing extremity so that the patient can make the best use of the prosthesis from that time onwards. In addition, the thought that there will be some extremity after the operation which friends and visitors can see, to some extent cushions the mental trauma of the amputation and on occasion, when the operation is performed for malignant disease, may enable the patient to accept the advice for this radical treatment more readily.

Three patients are described in whom upper limb amputation was performed and an upper limb prosthesis fitted immediately which was worn continuously from that time onwards.

Case reports

Case 1: H. M. aged 12 years. One year previously a swelling of the left wrist had been biopsied and a diagnosis of osteosarcoma was made which was treated by radiotherapy with cobalt-60 to a total tumour dose of 6000 R. For 6 months prior to his admission to Queen Mary's Hospital, Roehampton, the left wrist, palm and dorsum of the hand had been swollen and the patient had been unable to supinate or pronate the left forearm. His general health, however, remained completely satisfactory. At that time a hardened swelling was noted around the left wrist, and a soft swelling over the medial part of the palm and over the fourth and fifth metacarpals. An X-ray of the forearm showed that there was less sclerosis in the radial shaft than had previously been seen and the appearances were those of osteogenic sarcoma modified by radiotherapy. A chest X-ray showed no abnormality.

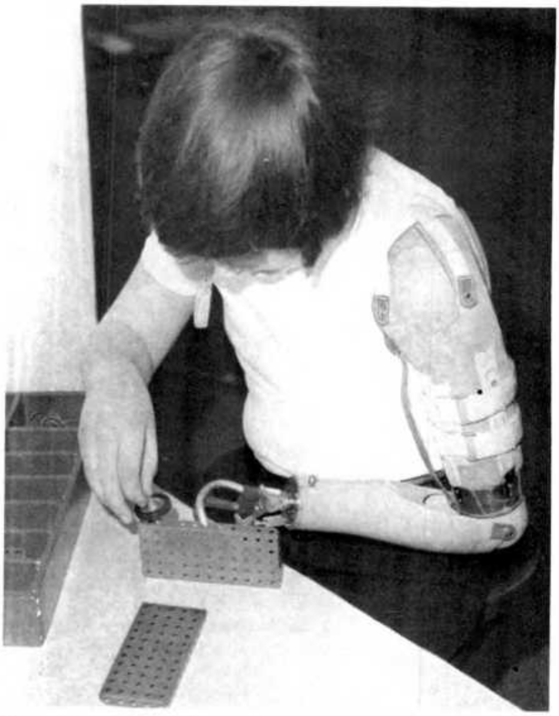

Fig. 1. *Case* 1. Learning to use the split hook on the third postoperative day.

On 6 February 1973 a left above-elbow amputation was performed (K. P. R.) under a general anaesthetic, using equal flaps and a level of bone section 10 cm above the medial epicondyle. The end of the humerus was filed to a rounded outline and the flexor and extensor muscle groups were sutured over the bone end to constitute a full myoplasty. All the major nerves were sectioned above the level of amputation and all vessels were ligated. The skin was closed with interrupted fine nylon sutures and no drainage was provided. The stump was bandaged with a thin crêpe bandage and the above-elbow prosthesis was applied on the operating table. After operation the prosthesis was removed for inspection of the wound on the second postoperative day and replaced without difficulty. The patient made increasing use of the prosthesis, wearing the

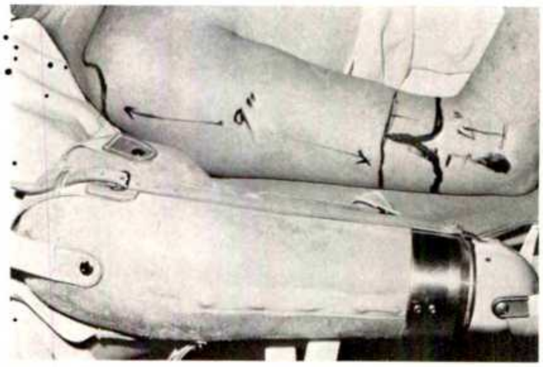

Fig. 2. *Case* 2. Skin incision marked before operation. All the measurements were checked with the prosthesis which had been supplied the previous day.

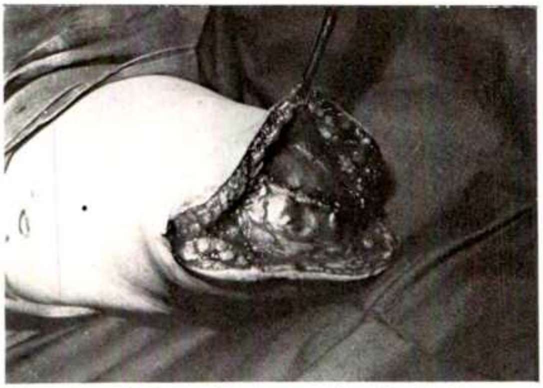

Fig. 3. *Case* 2. Above-elbow amputation showing the myoplastic attachment of flexor and extensor muscles over the bone end.

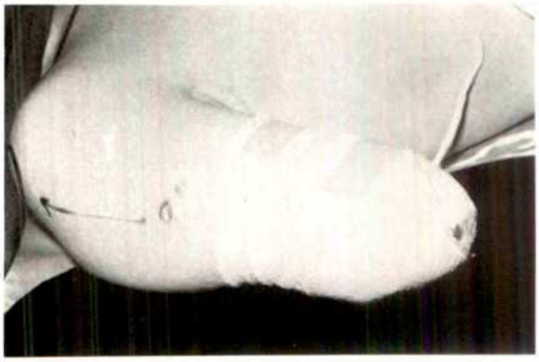

Fig. 4. *Case* 2. Completed stump covered by single crêpe bandage.

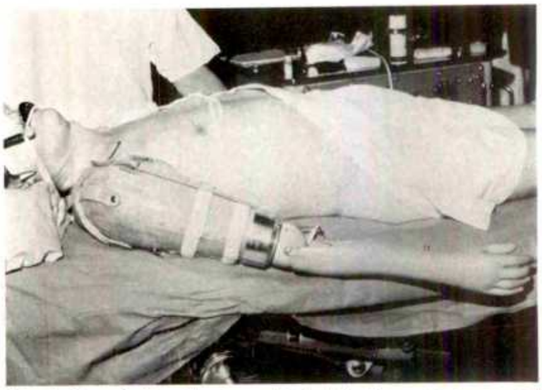

Fig. 5. *Case* 2. Prosthesis applied while the patient was still anaesthetized. A Plastazote shell covered the bandage, under the prosthesis.

cosmetic hand at all times except when he was using the split hook for everyday tasks. The wound healed without difficulty, and within 3 days of the operation the patient was using the prosthesis competently under instruction in the Arm Training School (*Fig.* 1). By the time of his discharge, 4 weeks after his operation, he was using the arm without difficulty and was able to return to school, where he has continued with his education, and he takes part in normal school activities.

One year after operation an opacity appeared in the left chest. Subsequent thoracotomy showed this to be a metastasis and the patient is currently completing a further course of radiotherapy to the chest. He has been supplied with a new prosthesis which he is using continuously for all normal activities.

Histological examination of the metastasis from the lung showed the appearances of a chondroblastic osteogenic sarcoma similar to those of the tumour in the resected forearm.

Case 2: D. B. aged 44 years. In 1955 this patient developed osteoclastoma of the right radius which was treated by curettage followed by radiotherapy to a dose of 3200 R which left the patient with good function and mobility. However, in the year prior to admission he developed increasing discomfort and pain with any undue use of the wrist. X-rays taken at that time showed increased bone destruction, but his chest X-ray remained clear. Biopsy taken then showed the changes of fibrosarcoma, and an isotope bone scan showed an area of increased uptake of strontium at the lower end of the right radius. Whole lung tomography failed to demonstrate any metastasis. Amputation was advised at a level which would clear the radius and ulna and the patient was transferred to Queen Mary's Hospital, Roehampton, where a prosthesis was constructed for an above-elbow amputation. The patient was introduced to the Arm Training School and the appliances which he would use with his prosthesis.

Operation (*Fig.* 2) was performed on 5 February 1974 (K. P. R.) Bone section was 22 cm from the acromion process and at this level equal flaps were cut. All the nerves were cut proximal to the line of bone section and the muscles distal to the line of section to enable a myoplastic closure across the bone end (*Fig.* 3). The bone end was carefully rounded with a bone file and all the muscle groups secured over it with catgut sutures. The deep fascia was sutured and the skin closed with interrupted nylon without any drainage. A small crêpe bandage was applied (*Fig.* 4) and covered by a Plastazote cuff and the prosthesis (*Fig.* 5). Three days later the patient was beginning to use his prosthesis and the wound healed without difficulty, the sutures being removed on the fourteenth day. The prosthesis was subsequently modified so that the Plastazote cuff was unnecessary, and the patient continued his arm training on an outpatient basis. He has become left-handed for the purposes of writing but is already able to drive his car and to manage tools such as a knife and fork with his split hook (*Fig.* 6). He wears the arm continuously during his waking hours and has continued to do so up to the present time, 11 months later.

Histology of the forearm showed a moderately well-differentiated fibrosarcoma with conspicuous mitotic activity. The appearance is that of a fibrosarcoma in an area of radiation for a previous osteoclastoma.

Case 3: V. W. aged 54 years. This patient was admitted in May 1971 with a history that a year previously he had sustained a chain-saw injury to his left wrist, dividing all flexor tendons except the flexor pollicis longus and all the extensor tendons together with both median and ulna nerves. The distal row of carpal bones at the bases of the metacarpals were also extensively damaged. The possibility of reconstructive surgery was extensively considered but eventually the patient accepted

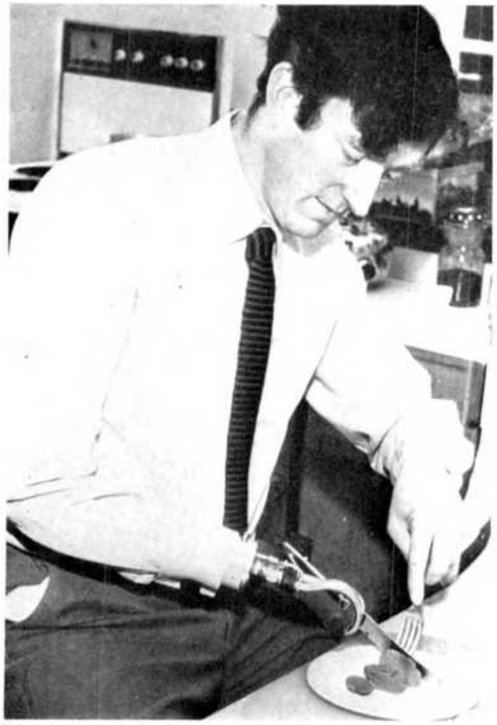

Fig. 6. *Case* 2. Using a knife and fork 2 weeks after operation.

that an amputation and prosthesis would give him the best functional result. The patient was self-employed as a chartered accountant and he was right-handed.

Operation was performed in May 1971 (B. G. A.) when anterior and posterior flaps were formed at wrist level and all tendons, vessels and nerves were divided. The radial styloid was removed and the flexor and extensor tendons were sutured over the bone ends. The wound was closed in layers with a Redivac drain. A soft gauze dressing was applied, covered with a bandage and a plaster socket constructed over this carrying a double hook (*Fig.* 7). A shoulder harness was attached. The wound healed without difficulty, and within 48 hours the patient was able to use his prosthesis (*Fig.* 8), and at the end of 18 days he had become efficient with the split hook which he used for all his everyday activities.

Six weeks after operation he received his definitive prosthesis together with a cosmetic hand. When reviewed 18 months after operation it was noted that he had made a great success of wearing the prosthesis and was using it for gardening, carpentry and driving his car. He was aware of a phantom limb but this caused him no distress.

Discussion

The technique of amputation was standard without involving any modification of the ordinary surgical procedure. The application of a hard shell to the wound dressing was shown to have no deleterious effect on wound healing. The ability of the patient to wear and use a prosthesis from the moment of operation has undoubted advantages.

The concept of immediate fitting of a prosthesis at operation is not new. Berlemont pioneered this technique with the lower limb in 1961 (Berlemont, 1964), soon followed by Dederich (1967) and Burgess et al. (1969), who have treated a large number of patients in this way. However, our own experience with immediate prosthesis fitting after lower limb amputation has confirmed the beneficial effect of immediate fitting and some of the advantages of a rigid socket bearing a prosthesis. We have, however, become aware of problems with pressure necrosis of skin flaps and the problems of infection under the rigid socket in the lower limb, but this has been in patients with arteriosclerotic disease of the lower limb in whom the vascular supply for the skin flaps has been critical, a situation which is not encountered with the upper limb where the amputation is usually performed for disease other than arterial insufficiency and the patients are not so old. Also, in the arm there is little chance of the wound becoming contaminated with *Clostridium* spores, so the risk of anaerobic infection is much reduced. Therefore the use of an immediate prosthesis appears to carry very little risk to the primary healing of the patient's stump.

The number of patients who can be seen in everyday life who are not wearing an upper limb prosthesis is evidence of the speed at which patients become one-handed, even when the dominant hand is lost. Once this has occurred, the most enthusiastic patient is unlikely to persevere to make an upper limb prosthesis work for him in his daily life. We therefore

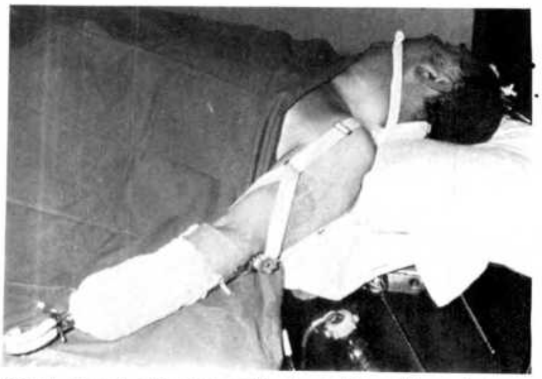

Fig. 7. *Case* 3. Through-wrist amputation with a plaster socket and harness applied while the patient was still anaesthetized. Suction drain tube and split hook can be seen.

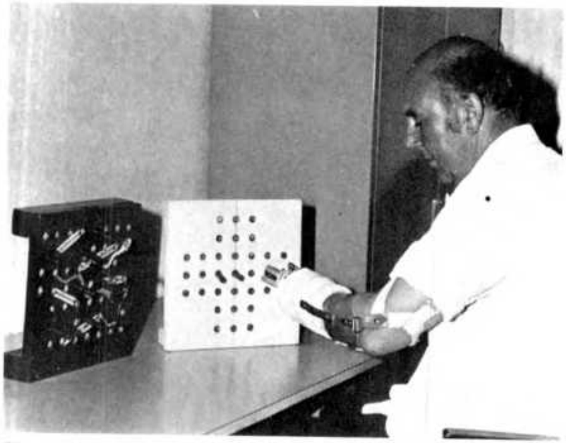

Fig. 8. *Case* 3. Learning to use the split hook on the third postoperative day.

consider it of great importance that the patient is never allowed to become one-handed in his cerebral representation and his mental processes. The instantaneous replacement of the amputated limb with a prosthesis appears to be the most rational way of achieving this end.

All the reported cases attended the Arm Training School within 2 or 3 days of their operation and were already learning to use a split hook before the sutures were removed, with the result that a knife and fork or simple tools could be used at the time that the patient was discharged from hospital. All the patients were wearing their arm throughout their waking hours when they were discharged from hospital and have continued to do so since. The patients who had an above-elbow amputation have had a formal prosthesis made prior to the amputation, while in the third patient a plaster socket was formed on the operation table on top of a soft surgical dressing, and the split hook and attachment were incorporated in the plaster so that the whole could be retained with a harness and shoulder band. Thus, the split hook could operate from the time that the patient regained consciousness. There was no problem in removing and replacing the socket until the time that the definitive prosthesis was constructed.

This follows the method used by Seddon (1966), when a plaster socket and prosthesis were applied at the time of an above-elbow amputation which was combined with a shoulder arthrodesis. Sarmiento et al. (1969) reported a further 4 cases. Loughlin (1969) used the technique in a bilateral arm amputation. Tooms (1972) discussed the advantages of the method and clinic reports of its use in the treatment of a large number of patients. He drew attention to the value of suction drainage and referred to the problem of distal oedema which may result if proximal constriction is inadvertently applied by the dressing, bandage or socket. He suggested that a plaster socket is most suitable for below-elbow amputations while a conventional prosthesis can be used for amputations at above-elbow level.

Conclusions

There appears to be no surgical disadvantage in applying a prosthesis to an upper limb amputation on the operating table and the benefit to the patient is unquestionable. For amputation below the elbow a plaster socket is the most satisfactory, but above this level a prosthesis can be made prior to the operation and applied over the surgical dressing.

Acknowledgements

We would like to thank the surgeons who referred these patients to the Westminster Hospital Group for their permission to publish these cases, the Department of Health and Social Security for allowing access to the Limb Fitting Service files, the Photographic Department at Queen Mary's Hospital, Roehampton, for the illustrations and Miss R. Clark for typing the manuscript.

The bacteraemia associated with burns surgery

C. H. BEARD, C. D. RIBEIRO AND D. M. JONES*

SUMMARY

Fifty-four surgical procedures on 39 burnt patients were studied with serial blood cultures. In 25 (46 per cent) of these procedures the cultures were positive. In spite of the absence of prophylactic systemic antibiotics there were no clinical manifestations and not one of the bacteraemias developed into a septicaemia.

The role of natural immunity in controlling the bacteraemia is discussed and it is suggested that prophylactic systemic antibiotic therapy covering burns surgery is unnecessary in the presence of normal immunoglobulin levels.

BACTERAEMIA frequently accompanies the manipulation of infected tissues. This phenomenon has been well documented in relation to procedures in dentistry (Felix et al., 1971), otorhinolaryngology (Herzen, 1971), surgery on the large bowel (LeFrock et al., 1973) and operations on the genito-urinary tract (Sullivan et al., 1973). We have investigated the possibility of bacteraemia occurring when the burn wound in patients is manipulated during surgical procedures.

Patients

Fifty-four unselected procedures under general anaesthesia on 39 burnt patients were studied by serial blood cultures. All the patients were inpatients at the Manchester Regional Burns Unit at Withington Hospital. The treatment policy at the time of this study consisted of closed dressings followed by varying degrees of active slough removal, from shaving excision with a grafting knife to blunt dissection with or without immediate grafting. These procedures were carried out between the tenth and fiftieth days after burning. During the period of the study no systemic antibiotics were used routinely and neither topical silver nitrate nor Sulfamylon nor silver sulphadiazine were used. In order to establish the immune status the immunoglobulin levels were measured in some patients.

The patients studied had deep burns extending to up to 60 per cent (average 15 per cent) of the body surface and were between the ages of 14 and 86 years (average age 45·5 years).

Methods

During this investigation burns were swabbed routinely once each week. The organisms isolated were characterized by standard methods and these results were used to establish whether organisms grown from blood cultures were also present on the burn wounds.

Blood cultures

Blood samples were taken only from veins selected to be away from the burned areas so that the possibility of skin contamination by colonizing bacteria was minimized. Most commonly veins in the back of the hand were used. The skin was prepared by swabbing with 70 per cent isopropyl alcohol and allowing this to dry before venepuncture. Ten ml of blood were collected immediately preoperatively and then intermittently during the procedure, but usually after 5 minutes and then at 15-minute intervals until the end of the procedure.

Castaneda broth culture

Two ml of blood were added to a bottle containing a slope of 15 ml of blood agar base no. 2 stiffened by the addition of 0·5 per cent Ionagar no. 2 (Oxoid L12) and covered by 70 ml of brain heart infusion broth containing 0·03 per cent Liquoid (sodium polyanethol-sulphonate).

Pour plate

One ml of blood was added to 9 ml of brain heart infusion broth (Oxoid CM225) containing 0·5 per cent white saponin and 0·5 per cent trisodium citrate. This was then added to 10 ml of molten-cooled double strength blood agar base no. 2 (Oxoid CM271) poured into a plastic Petri dish and allowed to set.

Filtration

The remaining 7 ml of blood were added to 100 ml of 0·05 per cent aqueous Triton 100 containing 0·5 per cent sodium carbonate. This was transferred, using a sterile syringe and needle, to a Sterifil filter system (Millipore) containing 45-mm membrane as soon as possible after being taken. After filtration by suction the membrane was washed with a total of 60 ml of nutrient broth. The filter carrier was then opened in a bacteriological cabinet and the membrane was transferred aseptically to the surface of a blood agar plate.

All the cultures were incubated aerobically at 37 °C. The pour plate and the membrane were inspected at 18 hours and again on the second day and discarded if there was no growth. The broth culture bottles were examined daily for growth for 7 days and if no growth was visible they were subcultured on the seventh day.

Immunoglobulin estimation

IgG and IgM levels were measured by a radial diffusion method using Hyland Immuno-Plate plastic

slides. The results were calculated from a graph using the results of known standards. The limits of normality accepted were those proposed by Hobbs (1970).

Results

Bacteraemia was detected during 25 out of 54 procedures; no growth was obtained in any of the 50 preoperative cultures. Bacteria were grown from 38 out of 111 (34 per cent) cultures taken at operation. A single bacterial species was grown in 13 operations, 2 in 11 and 3 in 1. *Table I* shows the frequency with which various organisms were isolated. All the organisms were present on the burn wound or had been isolated shortly before the operation.

On 13 of the samples quantitative cultures were performed; the numbers of organisms ranged from 1 in 7 ml of blood to 16 organisms per ml, the average being 1 organism to 3 ml of blood (*Table II*).

When an organism was grown on more than one occasion during a procedure the positive cultures were usually close together (*Fig.* 1).

The clinical course of patients who had had a positive blood culture was compared with those who had not. The mean twice daily temperatures for 48 hours before and after the day of operation were compared and the greatest difference in the mean temperatures was not found to be significant (P = 0·25) (*Fig.* 2). Shock, hypotension or rigors were not seen. *Figs.* 3 and 4 show the distribution of the ages and the size of the original burn in the two groups; it must be stressed that the total raw area at the time of the operation was sometimes small.

The nature of the operations was compared in the two groups. Twenty-one of the operations lasted for more than 1 hour and of those, 13 (62 per cent) developed a bacteraemia, while only 12 of the 32 shorter operations did (37 per cent). Breach of the granulation tissue barrier was also recorded. This barrier was

considered broken when the burn was excised, opening up tissue planes. This happened in 12 of 26 (46 per cent) procedures, producing bacteraemia, while its preservation by conservative slough removal liberated detectable bacteria in 13 out of 27 cases (48 per cent).

In *Figs.* 5 and 6 the IgG and IgM levels are plotted against the day of operation, with the range of normal levels indicated. Included in these figures are the immunoglobulin levels at the time of operation of 2 patients not in the series who subsequently developed septicaemia shortly after surgical procedures on their burns.

Discussion

The study has shown that bacteraemia is a frequent occurrence in burns surgery and that the organisms, being present on the wound at the time of operation or shortly before, are likely to have originated from the burn wound. It is suggested that the bacteraemia was not the chance detection of a few randomly liberated organisms, as in 9 out of 25 operations accompanied by bacteraemia the same organisms were grown on two or more different occasions during the procedure; they are more likely to have been liberated over a period of time during the operation. An attempt was made to establish how various factors influenced the occurrence of bacteraemia. We have no direct evidence of the degree of wound infection other than the presence of the organisms on the burn, but we were unable to detect any significant difference between the mean temperatures of the groups of patients from whom positive or negative blood cultures were obtained during the operation for the 48 hours before the procedure. There was an association between increase in age of the patient and the development of a bacteraemia. The area of the original burn also influenced the occurrence of bacteraemia, though at the time of the operation the raw area was often small. There was a tendency for longer operations to be associated with a bacteraemia, although this was not significant ($P = 0{\cdot}14$). The technique used in the operation was less important; the preservation of an intact 'granulation tissue barrier' did not prevent a bacteraemia developing, nor did its violation by shaving excision (Janzekovic, 1970) or radical excision down to the deep fascia regularly produce bacteraemia.

The immune status of some of the patients was assessed by measuring the serum IgG and IgM levels at the time of operation. These were all found to be normal, probably because the operations were all performed relatively late (after the tenth day) so that the depression (Munster et al., 1966) associated with burning had passed.

The major finding of this study relates to the effects of the bacteraemia. None of our patients was treated with prophylactic systemic antibiotics and yet the organisms disappear spontaneously from the circulation. More significant was the complete absence o clinical manifestations; in many studies on the bacteraemia produced by manipulations of infected tissues, shock, hypotension and rigors have been reported. Sullivan et al. (1973) reported that half o the transurethral prostatectomies that were associated with positive blood cultures produced these symptoms Our patients, in contrast, did not have these symptoms despite the fact that we recovered approximately similar numbers of organisms from the bloodstream Further, we were unable to demonstrate any significant difference in the mean temperatures of the two groups in the first 48 hours after operation.

Thus, the patients have dealt with the challenge o the bacteraemia unaided, presumably by the natural immune defences against the organisms concerned Two patients not in the series who had developed septicaemia shortly after a surgical procedure wer studied retrospectively. These operations had bee performed relatively early after burning and as can b seen from *Figs.* 6 and 7 where the IgG and IgM level have been plotted against the time of operation bot of these were low or at the lower limit of norma We interpret these findings as reinforcing the view that the normality of the immune status was importan in protecting our patients in this series from the effec of the bacteraemia.

It is suggested that routine systemic antibioti therapy has no part in preventing the establishmen of systemic bacterial infection when patients ar operated upon later than 10 days after sustaining th burn.

Acknowledgements

We are grateful to the consultant plastic surgeons at Withington Hospital for permission to study the patients under their care.

From an address given by Sir William Thomson at the Opening of the Physical and Chemical Laboratories in University College, Bangor, North Wales, on 2 February 1885.

THERE is this which is satisfactory about it [laboratory investigation] that perseverance is sure to be rewarded. There is no failure in physical science. We do not always find the particular thing looked for; we often find that what we looked for does not exist, or that something else exists very different from what we expected to find; but that something is to be found in any investigation entered upon with intelligence and pursued with perseverance is a certainty.... Every additional knowledge of the properties of matter is of value.

A rabbit model of perforated appendicitis with peritonitis

D. W. KING, J. F. GURRY, R. B. ELLIS-PEGLER AND B. N. BROOKE*

SUMMARY

No satisfactory animal model simulating acute perforating appendicitis followed by peritonitis in man has hitherto been achieved. A technique has been developed in New Zealand White rabbits to fulfil these desiderata. The bacterial flora associated with the ensuing peritonitis is similar to that found in man both as regards aerobes and anaerobes and their concentrations. The method effectively produces the required model in 70 per cent of rabbits subjected to the experiment. Satisfactory postoperative survival is achieved enabling therapeutic studies.

PRODUCTION of peritonitis experimentally, similar to that in humans, has always been difficult. We have attempted to produce an animal model of peritonitis akin to the human situation.

Materials and methods

Thirty-two New Zealand White rabbits weighing approximately 3000 g were anaesthetized using pentobarbitone induction and maintained by gaseous agents (Hynd, 1975).

Through a lower midline incision the base of the appendix was tied with black silk thread, leaving the blood supply intact (*Fig*. 1). Using the same anaesthetic technique and the same incision, further laparotomy was performed 18 hours after the first operation. If perforation had not occurred spontaneously the appendix was incised near the base, allowing the contents to enter the peritoneal cavity. The wound was then closed. Six hours later, using a gaseous anaesthetic only, appendicectomy was performed through the same incision.

The rabbits were weighed immediately before operation and at the same time each subsequent day.

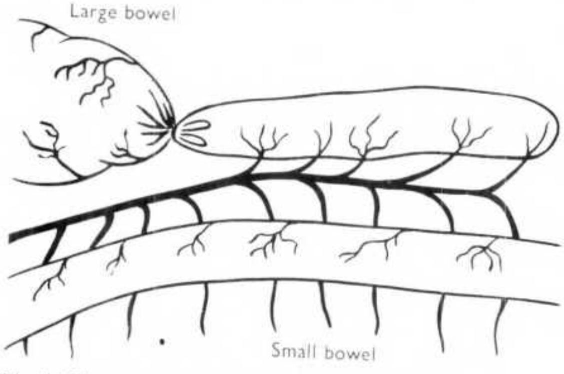

Fig. 1. Diagram showing the method of producing appendicitis.

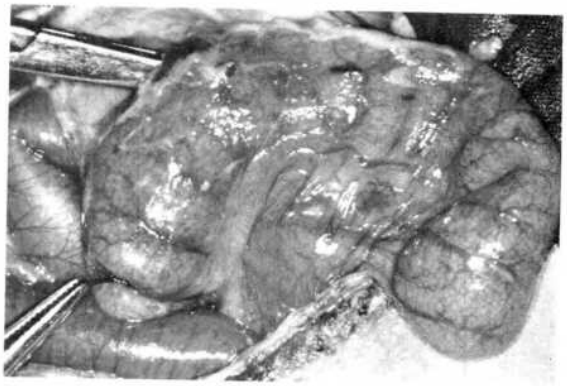

Fig. 2. Appearance of an appendix at the second operation. The upper pair of forceps is inserted through the perforation and the lower pair is holding the base tie.

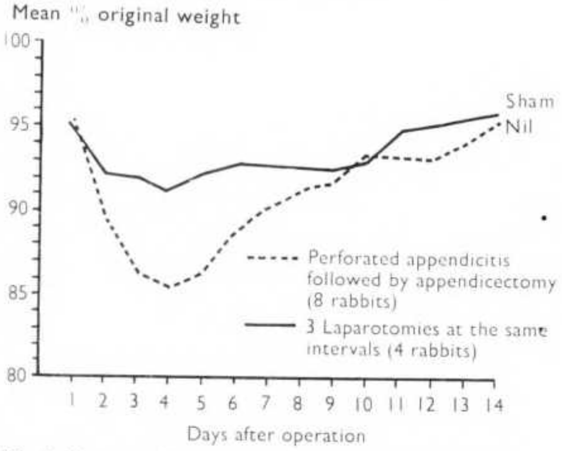

Fig. 3. Postoperative weight changes of the experimental animals compared with those of the controls.

Results

Twenty-eight of the 32 rabbits (87·5 per cent) survived the series of operations and for 36 hours postoperatively; 71 per cent (20 out of 28) of the appendices in the surviving rabbits had perforated spontaneously by the time of the second operation (*Fig*. 2). Of the 28 surviving rabbits, 19 were used in a study which is the subject of another report; 89 per cent (8 out of 9) of the remaining surviving rabbits lived for at least 14 days and were killed during the third week. Post-mortem examination showed a diffuse purulent peritonitis with many adhesions resulting in multiple abscesses throughout the peritoneal cavity, particularly

Present address of D. W. King: St Mark's Hospital, London.

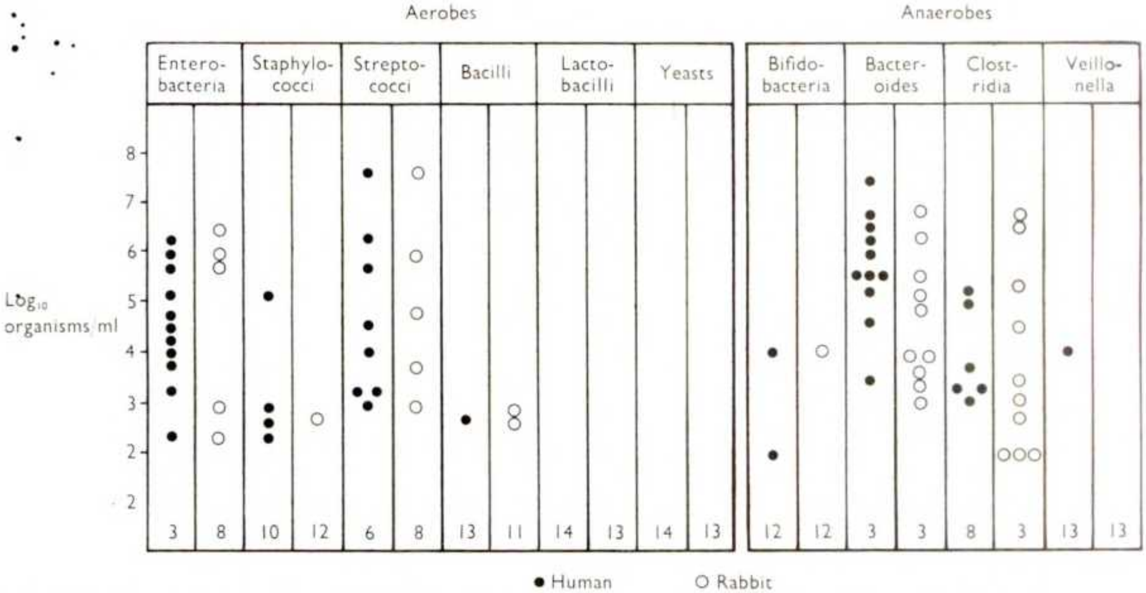

Fig. 4. Comparison of the organisms isolated from 13 rabbits with perforated appendicitis with those in pus found in 14 patients at operation for perforated appendicitis. The number at the base of each column is the number of specimens with a concentration of less than 100 organisms/ml.

the caudal half. Post-mortem examination of the rabbit dying on the third postoperative day showed purulent peritonitis.

Three rabbits in which only a base tie of the appendix was performed had died by 30 hours postoperatively. Tying less of the appendix produced less predictable results; if insufficient was tied, only a localized abscess, without mortality, resulted.

Four control rabbits had laparotomies performed at the same intervals, and at each operation the appendix was brought out on to the abdominal wall for a short time and then replaced. All 4 survived for at least 14 days and lost less weight than the rabbits with peritonitis (*Fig.* 3); no abnormality was found when they were sacrificed. The rabbits with perforated appendicitis followed by appendicectomy lost weight for 4–5 days, then regained weight to reach preoperative levels in the third postoperative week (*Fig.* 3).

Bacteriology

In 13 rabbits, 9 with spontaneous perforations and 4 with artificial perforations, culture of peritoneal fluid present at the third laparotomy was begun within 5 minutes of removal of the sample from the peritoneal cavity. Since the bacterial groups expected in the human situation include enterobacteria, staphylococci, streptococci, bacilli, lactobacilli, yeasts, bacteroides, bifidobacteria, clostridia and veillonella, these organisms were sought in the samples. The viable counts of the bacteria were expressed as $\log_{10}$ organisms/ml of peritoneal fluid; the lower limit of detection of bacteria with this method was 10^2 organisms/ml of fluid (Ellis-Pegler et al., 1975).

A comparison has been made of cultures from 13 animals with those in pus taken at operation for perforated appendicitis with purulent peritonitis in 14 patients (Pickersgill and Ellis-Pegler, 1975) (*Fig.* 4). The distribution was found to be similar; veillonella is an organism not found in the rabbit gut and was only grown from 1 human case.

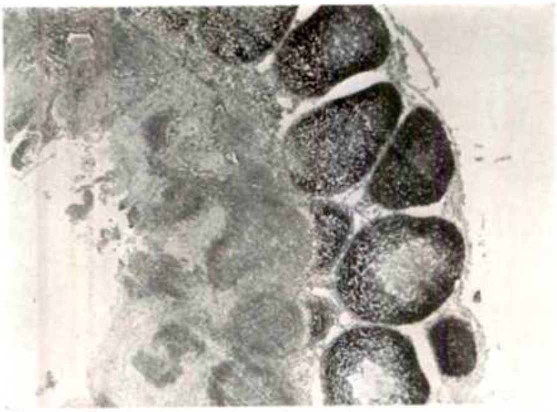

Fig. 5. Histological section of a rabbit appendix showing features similar to those of acute appendicitis in man.

Histology

Histologically, the appearances were similar in all the specimens examined and had many features in common with those seen in acute appendicitis in man (*Fig.* 5). However, in the rabbit suppuration was generally less pronounced and less evenly distributed throughout the wall and there was a zone of suppurative necrosis extending from the mucosa into the superficial parts of the lymphoid follicles. The latter is not seen normally in the human where the process seems to start from a focus rather than diffusely. There was also more lymphoid tissue in the rabbit appendices.

Discussion

Induction of peritonitis in animals by intraperitoneal injection of bacterial suspension alone has proved to be difficult (Browne and Stoller, 1970). Furthermore, rats and mice are relatively resistant to induction of Gram-negative peritonitis (Burnett et al., 1957; Browne and Stoller, 1970). In 1964 Schumer et al. used an injection of a known amount of *Escherichia coli* into the peritoneal cavity of guinea-pigs. Artz et al. in 1962 used pooled filtered faecal suspension, producing at least an 80 per cent mortality rate at 24 hours in dogs; variations on this method have been used often Filler and Sleeman, 1967; Lavigne et al., 1974). Burnett et al. (1957) removed a 3-mm ellipse from the colon of guinea-pigs and found that this routinely produced a severe diffuse peritonitis with an 85 per cent mortality rate. Zintel et al. (1950) induced peritonitis by ligating the appendiceal vessels and the base of the appendix and contaminating the peritoneal cavity with the appendix opened longitudinally; the abdomen was then closed. In 1938 Bower et al. described the technique of isolating and then tying the base of the caecal pouch of dogs, allowing the appendix to perforate spontaneously to produce a spreading peritonitis which in a later series produced a mortality of 78 per cent in untreated animals (Crook et al., 1968). The method was modified by Silvani et al. (1947) to include crushing of the wall of the appendix.

The methods used in injection of known bacterial suspension or perforating the bowel release organisms suddenly into a normal peritoneal cavity, and do not simulate the situation of acute obstructive appendicitis with perforation in humans. The method of Bower et al. (1938) and its subsequent variation (Silvani et al., 1947) involve the production of gangrene of the appendix by tying the blood vessels and do not include removal of the appendix. Neither of these reflect the human situation.

To overcome these objections a model has been created akin to the disease process in man. It is recognized that the faecal and colonic flora of rabbits and man are not identical. Nevertheless, with isolation and identification techniques widely used in human studies the same bacterial groups have been isolated from rabbit and human faeces, although in different concentrations and with some exceptions (Williams-Smith, 1965; Hawksworth et al., 1971). Perforation of the appendix is followed by peritonitis similar in bacteriological flora and degree of contamination to the situation found in humans. Moreover, the immediate effect in the animal is not so overwhelming as to produce rapid death, and this permits assessment of the postoperative course; the degree of peritonitis appears to be reflected in weight loss. Since perforation of the appendix is achieved in 70 per cent of animals the rate of reproducibility of the model is acceptable. If a high mortality is required for study, ligation of the appendix alone without subsequent removal may be undertaken; in this circumstance therapeutic measures under trial should be instituted after 24 hours.

The effect of noxytiolin in experimental peritonitis

D. W. KING, J. F. GURRY AND B. N. BROOKE*

SUMMARY

The evidence for the value of noxytiolin (Noxyflex) in peritonitis is contradictory. In a controlled trial of the effect of noxytiolin in peritonitis in rabbits we have found a significant increase in mortality in the trial group compared with a control group, but no significant difference when a dose equivalent to the recommended human dose is used. The postoperative course is adversely affected in the animals receiving noxytiolin.

NOXYTIOLIN (Noxyflex, Geistlich) has gained acceptance as a therapeutic agent in peritonitis with little objective evidence of its value. It has a different chemical structure from other antibacterial or antimycotic agents and its mode of action has not been determined. A possible explanation of its action is its chemical similarity with methyl-mustard oil, which has a considerable Gram-positive and Gram-negative antibacterial spectrum due to transaminase inhibition. Another theory is that intact noxytiolin may penetrate the bacterial cell membrane and dissociate intracellularly into methyl-thiourea and formaldehyde.

According to Browne and Stoller (1970) intraperitoneal injection of noxytiolin offered significant protection against a lethal Gram-negative peritonitis induced with proteus and coliform organisms in guinea-pigs. They also presented a series of patients with faecal peritonitis with a low mortality rate, thought to be due, in part at least, to an instillation of 2·5–5·0 g into the peritoneal cavity at the time of operation.

However, Cleaver et al. (1974) were unable to show that lavage with noxytiolin was more beneficial than with Hartmann's solution in faecal peritonitis in rats.

We have performed a controlled trial of the effect of noxytiolin in experimental peritonitis in rabbits.

Materials and methods

Peritonitis was induced in 40 New Zealand White rabbits by the method previously described (p. 642 of this Journal), with 35 survivors which were treated as follows. At the time of appendicectomy either nothing further was done or 5 ml of one of the following solutions were instilled into the peritoneal cavity: normal saline, 2·5 per cent noxytiolin or 10 per cent noxytiolin, the noxytiolin being mixed immediately before administration. Thus, control and trial groups were obtained (*Table I*). The animals were weighed at the same time each day.

Results

The mortality for each group is shown in *Table I*; it was higher in the rabbits receiving noxytiolin, the difference between the trial and control groups being significant at the 5 per cent level (Fisher's exact probability test).

The 3 deaths in the control group occurred on the second postoperative day, but in the noxytiolin group while 7 died during the second postoperative day, the remaining 3 deaths occurred later, between the eighth and eleventh postoperative days. At autopsy all had diffuse purulent peritonitis; this had become walled off into abscess cavities in those dying after 7 days and in those surviving for 2 weeks.

A greater postoperative weight loss was seen in the trial group compared with the controls, and this is significant ($P < 0·01$) when subjected to the sign test and analysis of variance (Seigal, 1956) (*Fig.* 1). The 13 rabbits dying postoperatively are excluded; those dying in the first 2 days lost weight at the same rate as the rest, but those dying later lost more weight generally, falling as low as 67 per cent of the preoperative weight in two instances.

A comparison of peripheral blood levels of noxytiolin every 15 minutes for 1 hour following instillation of 5 ml of 10 per cent noxytiolin into a normal rabbit and one with peritonitis revealed an increased absorption of noxytiolin in peritonitis (*Fig.* 2). No significant blood levels could be detected following instillation of 2·5 per cent noxytiolin.

Table I: WEIGHT AND MORTALITY

Instillation	Group	No. surviving periop. period	Average preop. weight (g)	Mortality	
				No.	%
—	Control	8	3139	1	12·5
5 ml N saline		9	2583	2	22·2
	Total	17	2845	3	17·6
5 ml 2·5% noxytiolin		10	2882	5	50
5 ml 10% noxytiolin		8	2624	5	62·5
	Total	18	2768	10	55·6

Discussion

The evidence of the benefits of noxytiolin is contradictory; only Browne and Stoller (1970) have demonstrated any protection from peritonitis in experimental animals. The evidence of its benefits in clinical peritonitis comes largely from uncontrolled trials (Browne and Stoller, 1970; Pickard, 1972). We are at present conducting a double blind clinical trial in perforated appendicitis.

The dose of 5 ml of 2·5 per cent noxytiolin corresponds approximately to the recommended dose in

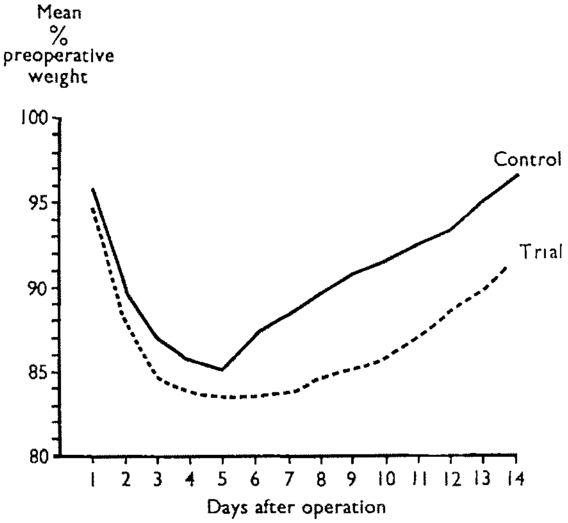

Fig. 1. Postoperative weight changes of the experimental group compared with those of the controls.

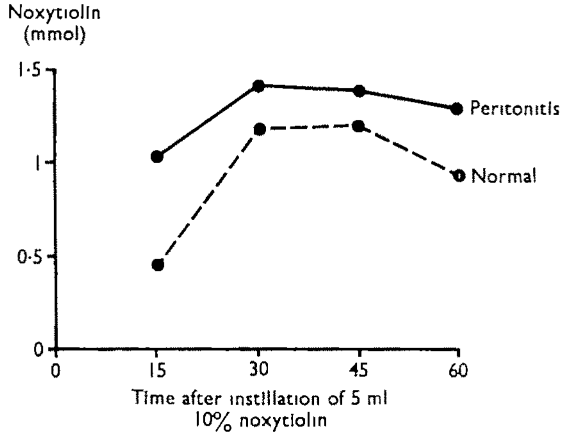

Fig. 2. Comparison of peripheral blood levels of noxytiolin after instillation of 5 ml of 10 per cent noxytiolin in a normal rabbit and in one with peritonitis.

humans of 100 ml of 2·5 per cent noxytiolin in adults. Compared with the control group there was a significant increase in mortality in the trial group, half of which received the recommended therapeutic dose and the other half of which received a higher dose. Though the higher dose did not significantly increase the mortality (*Table I*), it appears that toxicity increases *pari passu* with dosage, judging by weight loss (*Fig.* 3), which may possibly be attributable to the breakdown of the drug to methyl-thiourea and formaldehyde in the body. Browne and Stoller (1970) have shown that intraperitoneal injection of noxytiolin thrice weekly for 3 weeks in high doses produces patchy bronchopneumonia and cloudy swelling of the liver in Wistar rats. Moreover, the presence of peritonitis increases absorption (*Fig.* 2).

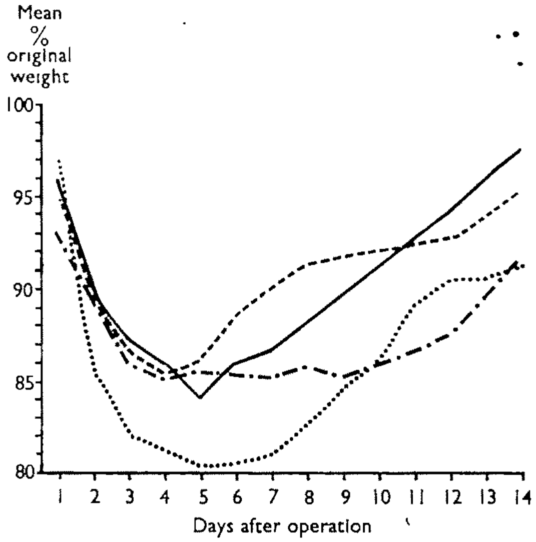

Fig. 3. Postoperative weight changes in the four groups:
——, no instillation; – – –, 5 ml of normal saline;
–·–·, 2·5 per cent noxytiolin; ········, 10 per cent noxytiolin.

Conclusion

Noxytiolin significantly increased the mortality in rabbits due to peritonitis from perforated appendicitis. There was also a significantly greater weight loss among the surviving rabbits of the trial group compared with the controls, which may be attributable to the increased absorption of the drug in peritonitis.

Acknowledgements

We would like to thank Dr I. Brown for estimating noxytiolin levels, Mr John Hynd for carrying out the anaesthesia, Miss M. Leighton of St Bartholomew's Hospital for statistical advice and the St George's Hospital Research Fund for financial support.

Results of modified Robert Jones operation for clawed hallux

E. I. M'BAMALI*

SUMMARY

The results of modified Robert Jones operation for clawed hallux carried out on 36 feet were reviewed by clinical and radiological investigations. Twenty-nine feet (80 per cent) achieved good results while 3 feet (8·5 per cent) obtained fair results and in 4 feet (11 per cent) the results were poor. Better results were obtained in the poliomyelitis cases than in the other groups.

Correction of deformity appears to be achieved by the transferred extensor hallucis longus elevating the first metatarsal neck and by the flexor hallucis longus flexing the rigid toe obtained by interphalangeal arthrodesis.

Tendon regeneration which is associated with recurrent clawing remains a problem.

Internal fixation should be used for the interphalangeal arthrodesis.

CLAW toes with dorsal subluxation or dislocation of the metatarsophalangeal joints may be associated with painful callosities and disability unrelieved by conservative measures. In 1916 Robert Jones described an operation to correct this deformity in which the extensor hallucis longus was transferred to the first metatarsal neck, and it is now common practice to fuse the interphalangeal joint of the hallux as well. A review of the results of this operation carried out in Cardiff is presented here.

Patients

There were 26 patients treated between 1954 and 1968, thus providing a follow-up period of between 4 and 19 years, with an average of 10·9 years (*Table I*). There were 11 males and 15 females. Ten cases were bilateral whilst 16 had unilateral involvement, making a total of 36 feet available for review. Their ages at the time of operation ranged from 2 to 49 years, the average being 15 years. The majority of the patients were operated on in the second decade (*Fig.* 1). About half the cases (46 per cent) were secondary to poliomyelitis (*Table II*). The next biggest group was the idiopathic cases (38 per cent), while miscellaneous causes included 1 case each of Friedreich's ataxia, spastic hemiplegia, postmeningitic spasticity and congenital hemivertebra with scoliosis.

Average	10·9
Tendon regeneration	
Unilateral	3
Bilateral	3
Total	9

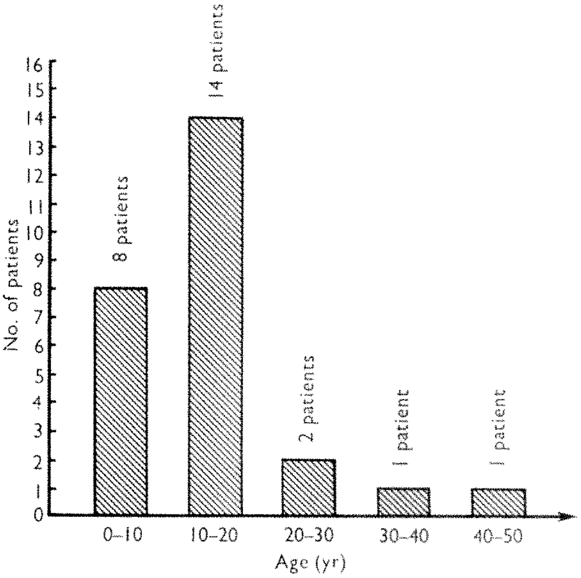

Fig. 1. No. of operations performed in each decade.

Operative method

The method used was standard. An L-shaped dorsal incision was used. The long extensor to the hallux was divided close to its insertion in the base of the distal phalanx. The interphalangeal joint was then arthrodesed by excising the articular cartilage of the phalanges, opposing the denuded surfaces and holding them fixed with catgut stitches passed through the remnants of the long extensor distally and the capsule proximally. No internal fixation was used. The proximal fragment of the divided long extensor tendon was then passed through a drill hole in the neck of the first metatarsal and sutured back to itself with the ankle in full extension. The foot was immobilized in a below-knee plaster for between 8 and 12 weeks.

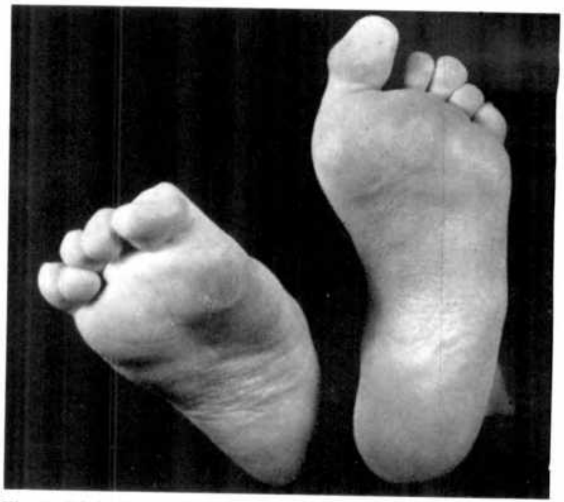

Fig. 3. Right hallux after operation demonstrating a poor result. Note the clawing of the hallux and the callosity over the first metatarsal head.

Table II: AETIOLOGICAL FACTORS

Aetiology	No. of cases	%
Poliomyelitis	12	46
Idiopathic	10	38
Miscellaneous		
Friedreich's ataxia	1	15
Spastic hemiplegia	1	
Postmeningitic hemiplegia	1	
Associated with congenital hemivertebra and scoliosis	1	

Total number of paralytic feet was 16 (poliomyelitis 12, miscellaneous 4) or 61 per cent.

Results

The primary aims of the operation are to correct deformity (clawing) and to relieve symptoms (pain, with or without callosities) in the hallux. The results based on the presence of postoperative deformity and symptoms were graded as follows:

Good: Deformity (clawing of the hallux) corrected and no symptoms.

Fair: Deformity not corrected but no symptoms.

Poor: Deformity not corrected and persistent symptoms present.

Using the above criteria 29 feet (80 per cent) obtained good results (*Table III*, *Fig*. 2), 3 feet obtained fair results and 4 feet (11 per cent) had poor results (*Table III*, Fig. 3). The age at operation or period of follow-up did not seem to affect the results.

Table III: RESULTS OF OPERATION

Result	No. of feet	%
Good (no deformity or symptoms)	29	80
Fair (no symptoms but clawing recurred)	3	8·5
Poor (clawing with symptoms)	4	11

Table IV: INCIDENCE OF FIBROUS UNION AND MALUNION

Type	No. of feet
Fibrous union	
Unilateral	3
Bilateral	4
Total	11 (31%)
Malunion	
In flexion alone	6
In medial rotation alone	6
In flexion and medial rotation	3
Total	15 (42·5%)

Five of the 29 feet classified as good results had symptoms from foot deformities unrelated to clawing of the hallux. These patients together with the 3 poor results were dissatisfied with the operation. In 7 feet (2 bilateral and 3 unilateral) clawing of the hallux had recurred. In 5 the extensor hallucis longus had regenerated. In 4 feet the persistent clawing was associated with both tendon regeneration and fibrous union of the interphalangeal arthrodesis.

In only 1 of the 7 feet with recurrent clawing was the aetiology poliomyelitis. In 3 the aetiology was unknown, while 1 was secondary to Friedreich's ataxia and 2 to spastic hemiplegia. Thus, better results were obtained in cases secondary to poliomyelitis.

Complications

Union of the interphalangeal arthrodesis

Seven patients developed fibrous union of the interphalangeal arthrodesis. Four were bilateral and 3 unilateral, making a total of 11 feet or approximately 31 per cent of all cases (*Table IV*, *Fig.* 4*a*). Union was bony in the rest (*Fig.* 4*b*). Only 1 case of fibrous union was symptomatic.

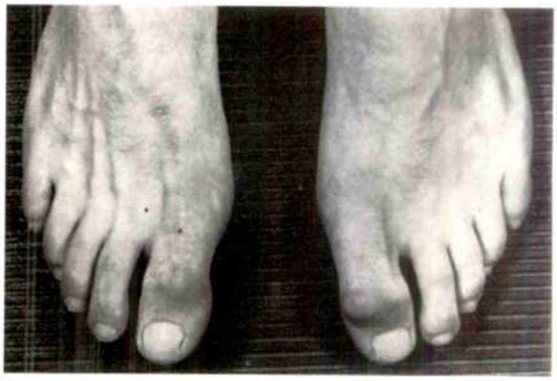

Fig. 5. Photograph demonstrating regeneration of the right extensor hallucis longus.

Malunion occurred in 11 patients, 4 bilaterally and 7 unilaterally. Thus, a total of 15 feet (42·5 per cent) had some degree of malunion (*Table V*). Malunion was in flexion in 6 feet, in medial rotation in 6 feet and in flexion with medial rotation in 3 feet. Three of the malunions in flexion developed asymptomatic adventitious bursae over the dorsum of the malunited interphalangeal fusion. In rotational malunions callouses developed on the volar surface of the medial side of arthrodesed interphalangeal joint. Thus, the sites of the adventitious bursae and callouses correspond to the points of pressure to be expected from the deformities. It is probably a question of time before painful symptoms develop at these sites as well.

Wound

There was no overt wound infection or early wound breakdown. Late wound complications included 2 cases of mild wound contractures and 1 case of hyperaesthesia of the wound and medial side of the hallux, presumably due to injury to the medial digital nerve at operation.

The metatarsophalangeal joint
All were examined radiologically and none showed any sign of osteo-arthritic changes. Clinically, only 1 of 18 feet examined showed stiffness of the joint.

Tendon regeneration
The extensor hallucis longus re-formed in 6 patients, 3 bilaterally, 2 on the left side and 1 on the right side. Thus, in a total of 9 feet (approximately 25 per cent of all cases) the tendon had regenerated (*Fig.* 5). This was associated with recurrent clawing in 5 feet (14 per cent).

Discussion

The results of this review show that a satisfactory result was obtained in 80 per cent, suggesting that it is a worthwhile procedure. The results were better in cases due to poliomyelitis than in other groups. From an analysis of the results it is possible to offer a comment on the mechanism by which correction is achieved. There are two possiblities. In the first, the transferred extensor hallucis longus tendon may act to elevate the first metatarsal neck as Robert Jones (1916) originally intended. Secondly, the addition of interphalangeal arthrodesis, apart from preventing flexion deformity of the interphalangeal joint, may also enhance correction of the clawing by achieving a rigid hallux upon which the long flexor tendon may act to reduce the extension of the metatarsophalangeal joint (Lambrinudi, 1938).

It would appear that both mechanisms were involved because, although there was a definite association between regeneration of the extensor tendon and recurrent clawing (the tendon had regenerated in 5 out of 7 feet with recurrent clawing), the fact that this was not invariably so when firm union of the interphalangeal fusion was achieved (in 4 cases out of 9) suggests that the second mechanism is also important.

It is obviously desirable that regeneration of the tendon should be minimized, and the technique of Ledge tenodesis described by Kirk et al. (1971) could possibly be adopted.

Fibrous union of the interphalangeal arthrodesis was also a problem in this series and although this was not often productive of symptoms in itself, because of its importance in helping to reduce the deformity, it would seem wise to adopt the technique of internal fixation with a medullary wire as suggested by O'Donoghue and Stauffer (1943).

Acknowledgements

I am indebted to Professor B. McKibbin for his help and advice in preparing this manuscript. I am grateful to Mr H. J. Richards and the late Mr Dylwyn Evans for allowing me to study their patients. I also wish to thank Mr C. Walker for the illustrations, and Mrs M. Hart and Miss C. Antonucci for their secretarial work.

Lymphosarcoma of the breast

CHARLES F. ROSS AND ARNOLD ELEY*

SUMMARY

A case of lymphosarcoma presenting as a breast tumour in a 68-year-old woman is described and the condition briefly reviewed.

IT is unusual for lymphosarcoma to present as a breast lump. The tumour reported here was at first thought to be primary, but the patient eventually died with generalized disease, as do the majority of patients with lymphosarcoma.

Case report

Mrs E. E., aged 68 years, presented with a lump in the lower quadrant of the right breast which she had first noticed 2 weeks before. On examination it was thought to be a carcinoma. No axillary lymph nodes were palpable and a simple mastectomy was done (A. E.) on 14 September 1966.

The pathology report (C. F. R.) was as follows: 'Simple mastectomy specimen 19×15×7 cm with a skin ellipse 19×10 cm bearing a normal nipple. An incision has been made into a firm, slightly lobulated, well-demarcated tumour, 3 cm diameter. On slicing, it is pinkish-grey and fleshy.'

It was thought to be a medullary carcinoma but microscopically proved to be a well-differentiated lymphosarcoma composed of mostly mature small lymphocytes, with a suggestion of follicular arrangement in places and invasion of the surrounding breast (*Fig.* 1). In some parts there was a good deal of fibrosis, with thick almost acellular bands. It was considered to be of low malignancy.

Exactly 2 years later the patient developed a subcutaneous lump over the left hip which macroscopically and microscopically closely resembled the breast tumour except that follicle formation was a little more evident and collagen less evident.

The patient continued in good general health, with a normal blood picture and no radiological evidence of dissemination until June 1971, when she developed an enlarged lymph node in the left groin. Histologically, the tumour was now anaplastic and resembled reticulum cell sarcoma, with much collagen formation (*Fig.* 2).

The patient was referred to Dr W. F. White at the Regional Radiotherapy Centre, St Luke's Hospital, Guildford, and was started on a course of chlorambucil 5 mg daily. She remained in good general health and chemotherapy was stopped in March 1972. The patient then moved from the district and remained well until the end of 1973, when she was found to have gross hepatomegaly, and chemotherapy was restarted. In spite of the latter the patient quickly deteriorated and died of bronchopneumonia on 4 July 1974. Necropsy (Dr G. B. Forbes) revealed an undifferentiated malignant lymphoma in the liver and spleen but no deposits elsewhere. The sections showed an appearance closely resembling that in *Fig.* 2.

Discussion

Sixty-eight cases of primary lymphosarcoma of the breast had been reported up to 1966, and Jernstrom and Sether (1967) described 3 further examples. Since then 50 more cases have been reported (Bellone, 1968; Boscaino et al., 1969; Yoshida, 1970; Freedman et al., 1971; Matsuyama et al., 1972; Seth et al., 1972; Wiseman and Liao, 1972; Case, 1973; Talvalkar, 1973). Freeman et al. (1972), in a paper considering extranodal lymphomas reported from 100 hospitals in the United States, had encountered 33 breast lymphomas in 1467 patients without disseminated disease when first seen. Haagensen (1971) had encountered 9 cases of the condition, and the total number now on record would appear to be 164 including that under discussion.

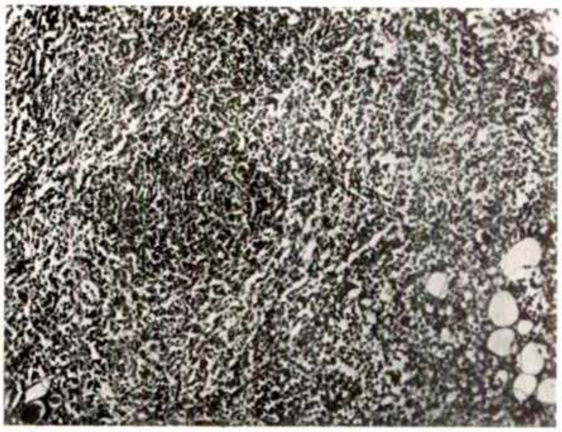

Fig. 1. Section of breast tumour. HE. (×106.)

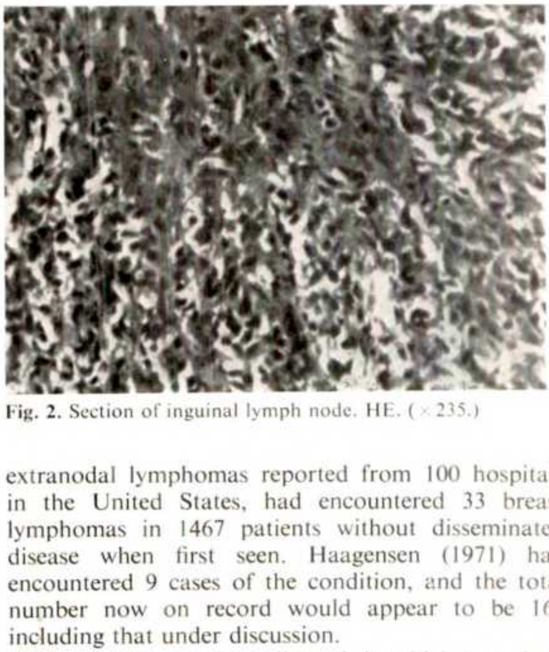

Fig. 2. Section of inguinal lymph node. HE. (×235.)

The disease may be unilateral, in which case there may be a single or several tumour nodules, or it may diffusely invade both breasts. A pregnant African Negress was recently described as having Burkitt's tumour affecting both breasts (Bannerman, 1966), but a similar condition has been reported outside Africa (Kay, 1955). When the tumour is solitary there is nothing to distinguish it clinically from carcinoma, but when a breast with several tumour nodules is encountered the possibility of lymphosarcoma should be considered. There is a definite predilection for the right breast. The age incidence is the same as that for carcinoma. The majority are in women and form about 0·2 per cent of malignant breast tumours in the female. Very few instances have been recorded in the male. A tumour nodule on one side may, after a period of many years, be followed by a similar lesion in the contralateral breast. Freedman et al. (1971) stated that bilaterality does not worsen the chances of survival.

---

* North West Surrey District Laboratory and Department of Surgery, St Peter's Hospital, Chertsey, Surrey.

Histologically, the growth may be well differentiated, as in the present case initially, or exhibit a varying degree of primitiveness through lymphoblastic to reticulum cell sarcoma. More than half the patients have involved axillary lymph nodes when first seen, but their presence and the size and number of tumours do not appear to be related to prognosis. The latter depends on the histological type, being best with lymphocytic and worst with reticulum cell sarcoma. It seems that the outlook is much better in lymphosarcoma than carcinoma whatever the treatment.

It is, of course, often difficult to know whether one is dealing with a primary or a secondary lesion, since sooner or later most of these patients have recurrences and it is impossible to be sure whether the original breast lesion is not the initial manifestation of a more generalized disease. However, it is distinctly uncommon for the latter to involve breast tissue (Milne and Maxwell, 1970) except in rapidly progressive lymphosarcomatosis occurring in pregnancy and the puerperium. In the more usual form of malignant lymphoma the natural history is quite different. Nevertheless, it appears that certain rare cases in which the breast is at first affected can be cured by mastectomy and the lesion is presumably arising as a primary in that organ.

Acknowledgements

Our thanks are due to Drs W. F. White, S. R. Drake (Kent and Canterbury Radiotherapy Centre) and G. B. Forbes (Kent and Canterbury Department of Pathology) for information regarding the treatment and subsequent course and for sections of the liver and spleen.

Surgical Research Society

The 21st Anniversary Meeting of the Surgical Research Society was held at Southampton on 10, 11 and 12 July 1975 with Professor A. P. M. Forrest (President of the Surgical Research Society) in the chair. The following papers were presented:

1. The effect of meat extract stimulation on serum gastrin of patients undergoing proximal gastric vagotomy alone (PGV) and with Finney pyloroplasty (PGVP)

W. H. S. PIGOTT (C. WASTELL), *Department of Gastroenterology and Surgical Unit, Westminster Hospital, London*

Serum gastrin concentration may be elevated when the gastric antrum is stimulated by food retained within the stomach. Fasting and Oxo-stimulated serum gastrin levels have been measured by means of radio-immunoassay in patients following (range 4–39 months, mean 25 months) PGV and PGVP in 19 and 23 male patients respectively.

The fasting levels after PGV and PGVP were 57·9±48·8 and 62·7±42·1 and the peak levels were 131·1±65·0 and 123·9±71·3 respectively (all values mean±s.d. pmol/l). No significant difference in either these levels or the shape of the gastrin response could be shown between PGV and PGVP.

Five patients, 1 following PGV and 4 following PGVP, with proved recurrent ulcers were also studied. Four of these had serum gastrin values similar to those found in patients without recurrence, but the fifth, who had a pyloroplasty, had hypergastrinaemia with a fasting level of 170 pmol/l and a peak level of 390 pmol/l. Antrectomy in this patient almost removed detectable serum gastrin to Oxo stimulation.

It is concluded that PGV does not result in either higher fasting or peak serum gastrin levels than PGVP and that although some recurrent duodenal ulcers are associated with elevated serum gastrin, the majority are not.

2. The treatment of superficial thrombophlebitis: a randomized double blind study using local heparinoid cream

P. P. MEHTA, S. SAGAR and V. V. KAKKAR, *Department of Surgery, King's College Hospital Medical School, London*

Superficial thrombophlebitis is a common complication of continuous intravenous infusion. Heparinoid cream (mucopolysaccharide polysulphate) has been shown to be absorbed into the circulation when applied to the skin and to produce a heparin-like action on blood clotting.

One hundred patients who developed infusion thrombophlebitis were randomly allocated to receive heparinoid or placebo cream for 5 days. The limbs were examined every day and changes in the local signs of thrombophlebitis recorded. The ^{125}I-fibrinogen test was used for quantitative assessment of the fate of the thrombus, and radioactivity at the site of thrombophlebitis was recorded every day for 5 days. Fifty of the 100 patients included received the placebo cream and 50 the heparinoid cream. The mean time required for the relief of local symptoms and signs in the placebo group was 126 hours (range 48–148 hours) while in the heparinoid group it was 58 hours (range 36–102 hours). The decline in percentage radioactivity in the two groups was as follows:

% Radioactivity

	Placebo group		Heparinoid group	
Day	Mean	Range	Mean	Range
1	100		100	
2	135·4	66–280	85·5	45–135
3	116·1	24–224	58·9	10–120
5	76·3	24–192	23·5	5–60

These results suggest that local application of heparinoid cream produces symptomatic improvement and assists in early resolution of thrombophlebitis.

3. Renal function before and after haemorrhage in rats with chronic bile duct obstruction: a micropuncture study

N. E. MOSS, MARY FRASER, C. J. RYAN, A. C. KENNEDY, MARJORIE E. M. ALLISON and L. H. BLUMGART, *University Departments of Surgery and Medicine, Glasgow Royal Infirmary*

In rats with biliary tract obstruction, renal ischaemia is consistently followed by severe acute renal failure (Dawson, 1964).

We have used micropuncture and light and electron microscopy techniques to study single nephron and whole kidney structure and function before and immediately after haemorrhagic shock in rats with chronic bile duct obstruction and in sham-operated control rats.

In vivo the kidneys of rats with common bile duct obstruction appeared abnormal, with deposition of pigment throughout the renal tubule cells and with intratubular debris and pigment. Urine flow rate, sodium excretion, whole kidney glomerular filtration rate, superficial single nephron filtration rate, glomerular capillary hydrostatic pressure and proximal fractional reabsorption were not significantly different in the two groups before haemorrhage. Renal plasma flow, however, was significantly increased and filtration fraction significantly decreased in rats with common bile duct obstruction. Free flow proximal intratubular hydrostatic pressure varied in the rats with an obstructed common bile duct (6–34 mm Hg), high pressures presumably being due to distal intratubular block.

Haemorrhage to 30 mm Hg for 30 minutes and retransfusion resulted in a significant diuresis and natriuresis, more marked in the control rats, but without a significant change in blood pressure or haematocrit. The superficial single nephron filtration rate fell significantly in both groups but especially in the jaundiced animals where there was also a parallel fall in glomerular filtration rate and renal plasma flow. No change in proximal fractional reabsorption was found. Hence, factors operating beyond the proximal tubule must be important in the diuretic response.

We conclude that chronic bile duct obstruction in the rat results in structural changes and subtle alteration in renal function with evidence of tubular obstruction, and that the response to haemorrhage is attenuated in these animals.

4. Blood viscosity studies in patients with Raynaud's syndrome

K. B. GOYLE and J. A. DORMANDY, *St James's and St George's Hospitals, London*

Whole blood and plasma viscosity measurements were carried out at 37 and 27 °C in 10 patients with Raynaud's syndrome as well as 10 normal controls. The Wells-Brookfield and the newly developed Contraves viscometers were used, which allowed measurements of viscosity to be made at a much wider range of shear rates than had hitherto been possible (from 0·7 to 230/sec). The patients were also assessed clinically, biochemically and by histological examination of full thickness skin biopsies from a finger pulp. The results at 37 °C were consistent and showed a small but significant increase in the relative viscosity of the patients' blood compared with the controls. More importantly, lowering the temperature to 27 °C increased the abnormality in the patients' blood considerably.

At 27 °C the mean blood viscosity, measured at a shear rate of 0·77/sec, of patients with Raynaud's syndrome was 22·5 ± 2·9 (s.d.) c.p.s. The comparable value for normal controls was 16·7 ± 2·6 c.p.s. (The difference has a P value of 0·05.)

These results suggest that the periodic digital circulatory insufficiency in patients with Raynaud's syndrome may be due to an abnormal increase in blood viscosity locally which is precipitated by a fall in tissue temperature.

5. Treatment of Raynaud's syndrome with stanozolol

P. E. M. JARRETT, M. MORLAND, G. CLEMENSON and N. L. BROWSE, *Department of Surgery, St Thomas's Hospital, London*

Patients with scleroderma and Raynaud's disease have been shown to have lowered blood fibrinolytic activity (Cunliffe and Menon, 1969). We have studied the effect on such cases of stanozolol, which enhances natural fibrinolysis.

Twenty patients have had their clot weight fibrinogen, dilute blood clot lysis time (DBCLT), plasma fibrinolytic activity (fibrin plate) and hand blood flow (volume displacement plethysmography) measured before and after 3 months of treatment with stanozolol tablets 5 mg b.d.

Fourteen patients completed the course and had no intercurrent operation or illness. Eighty per cent felt that their hands were warmer and they were having fewer Raynaud's attacks. All wished to start a second course of treatment after being off the tablets for 1–2 months. Eleven have recommenced treatment following 3 months without stanozolol.

	DBCLT (min)	Fibrin plate (mm^2)	Clot weight fibrinogen (mg/100 ml plasma)	Hand blood flow (ml/min $100\ ml^{-1}$)
Before stanozolol	417	385	387	5·5
After 3 months of stanozolol	176	371	258	10·8
Significance of change P (t-test)	0·01	0·87	0·001	0·001

The results after 3 months off treatment and a second 3 months of treatment will be reported.

These results show that enhancement of fibrinolysis and reduction of plasma fibrinogen induced by stanozolol may be beneficial in scleroderma and Raynaud's disease.

6. Comparison of pituitary function and clinical response after transphenoidal and transfrontal hypophysectomy for advanced breast cancer

T. BATES, R. D. RUBENS, R. D. BULBROOK, P. R. GOODWIN, D. Y. WANG, M. A. FALCONER, L. F. W. SALMON, P. H. SCHURR, O. H. SHAHEEN, R. K. KNIGHT and J. L. HAYWARD, *Imperial Cancer Research Fund Breast Cancer Unit, Guy's Hospital, London*

Transphenoidal hypophysectomy has been introduced as an alternative to the transfrontal operation for advanced breast cancer. The effect of these two operations on endocrine function has been compared.

Pituitary stimulation tests were carried out before and 10 days and 6 weeks after hypophysectomy. Ten patients had a transfrontal and 10 patients a transphenoidal operation. Thyrotrophin-releasing hormone (TRH) 400 μg and gonadotrophin-releasing hormone (LH-FSH-RH) 200 μg were given intravenously, and plasma FSH, TSH and prolactin (HPr) were measured at 0, 20, 30 and 60 minutes. Basal blood ketosteroids (DS and AS) were also determined.

After transfrontal hypophysectomy basal FSH, TSH, DS and AS concentrations were extremely low in the majority of patients and did not increase after stimulation. HPr levels were in the high normal range and in 2 cases there was a marked response to stimulation.

After transphenoidal hypophysectomy hormone levels were generally higher (2–10 times) than after the transfrontal operation, and stimulation led to marked increases in 8 of 10 cases. Basal HPr levels were again in the high normal range.

There were a similar number of clinical remissions in both groups but hormone levels did not appear to correlate with clinical response.

7. Oestrogen receptor activity in human breast tumours

R. A. HAWKINS, A. HILL, E. KILLIN, I. SMITH, M. MAUREEN ROBERTS, A. R. CURRIE and A. P. M. FORREST, *Departments of Clinical Surgery and Pathology, University of Edinburgh*

Oestrogen receptor activity has been determined by saturation analysis in 164 tissues. Activity was detected in 98 of 140 malignant breast tumours, whether primary or metastatic. The range of binding sites was 0·1–77·2 fmol/mg and the dissociation constant of binding 0·15–1·5 M.

Receptors were present in 5 of 24 benign breast tissues; in only one, a giant fibro-adenoma, was activity high (8·5 fmol/mg).

The incidence of receptor activity increased with experience and the concentrations were greater in postmenopausal than premenopausal women.

To determine if estimates were reproducible within a single tumour 10 large tumours were specially examined. Each was cut into sections, and two to three areas, the histology of which was defined, were selected for receptor assays. Although there was considerable variation in receptor concentration, averaging 2·3 times, there was no difference as far as the presence or absence of receptor activity was concerned. An oestrogen receptor assay on a single portion of tumour may have qualitative but not quantitative relevance.

8. Factors which influence the location of atherosclerosis. Is turbulence good or evil?

N. L. BROWSE, M. LEA THOMAS and A. E. YOUNG, *Department of Surgery, St Thomas's Hospital, London*

The disruption of streamlined flow at arterial bifurcations is commonly quoted as the reason for the high incidence of atherosclerosis at such sites, yet the most common site of atheromatous stenosis is the middle of the femoral artery at the adductor hiatus, where there is no bifurcation.

In a review of 50 arteriograms we found the external iliac, common femoral and lower popliteal arteries were least diseased. These segments cross joints.

We have measured the length and diameter of the popliteal artery across the extended and flexed knee joint by radiological and haemodynamic methods in 26 dogs. The artery shortens by 1·3 per cent/10° of flexion. The diameter does not change. Similar changes of length (2·2 per cent/10°) have been found during flexion of the knee and elbow in 11 men.

In a slow flow model, and in *in vivo* pulsatile flow, bending the vessels causes turbulence in the distal half of the bend.

We therefore postulate that repeated changes in length and turbulent flow keep the distal half of the external iliac and popliteal arteries free of atheroma. Atheroma occurs in bifurcations, the abdominal aorta, common iliac artery and adductor hiatus because these segments are fixed and flow is streamlined. Turbulence and movement are good not evil.

9. Early diagnosis of jaundice: a computer and clinical study

R. P. KNILL-JONES, K. M. COCHRAN, G. S. SOKHI, R. I. RUSSELL and L. H. BLUMGART, *University Department of Surgery and Gastroenterology Unit, Glasgow Royal*

Infirmary, and Department of Medicine in relation to Mathematics and Computing, University of Glasgow

Prospective studies have given encouraging results in the use of Bayesian statistics for the diagnosis of jaundiced patients (Knill-Jones et al., 1973). To evaluate their use further the system was studied prospectively on 40 patients from two specialist units with an interest in hepatic and biliary disease. A maximum of 60 items of routine clinical and laboratory data available within 48 hours of a patient's admission was collected on a standard form and the diagnosis was calculated by a computer program using likelihoods obtained from the earlier study. The accuracy was assessed by comparing the calculated 48-hour diagnosis of 1 of 11 diseases causing jaundice to the final agreed clinical diagnosis. In 16 patients the probability of the calculated diagnosis was $>0·96$ (accuracy 88 per cent), and in the remaining 24 patients with a lower probability the accuracy of diagnosis was 65 per cent. A simpler decision between a 'medical' or 'surgical' cause for jaundice in the same group of patients was also calculated and where the probability was $>0·96$ the diagnosis was correct in 27 out of 28 cases.

Although the computer diagnosis was no better than specialist diagnosis in this study, it has been shown to be more accurate than that of non-specialist clinicians (Stern et al., 1974), especially in situations where refined diagnostic facilities are lacking and there is a danger of early diagnostic laparotomy.

10. The influence of two methods of haemostasis on the rate of wound sepsis: a random controlled trial of ligature and diathermy

R. S. ARNOT, MARY EVANS and A. V. POLLOCK, *Scarborough Hospital, Yorkshire*

Four hundred years ago Ambroise Paré found that sepsis was less likely to develop in wounds in which bleeding vessels had been ligated rather than cauterized (Hastings, 1974). The incidence of postoperative wound sepsis after haemostasis by ligature or diathermy has not previously been studied.

In consecutive patients 248 clean and 308 potentially contaminated general surgical operations were randomized for haemostasis either by ligature or diathermy. In clean wounds the incidence of primary wound sepsis was not influenced by the type of haemostasis, but secondary sepsis (after discharge of a wound haematoma) was significantly commoner when ties were used (12 out of 134 or 9 per cent, compared with 1 out of 114 or 0·9 per cent; $\chi^2 = 8·092$, $P<0·01$).

In potentially contaminated operations control of primary sepsis depends both on aseptic techniques and effective chemoprophylaxis. In the present series when an adequate topical antibiotic was used the method of haemostasis made no difference to the infection rate. When, however, such an antibiotic was not used, ligature of bleeding vessels in the abdominal wall was associated with significantly less sepsis than was diathermy (34 out of 162 or 21 per cent, compared with 46 out of 146 or 31·5 per cent; $\chi^2 < 4·49$, $P<0·05$).

HASTINGS P. (1974) *Medicine: An International History*. London, Benn.

11. Impaired lymphocyte protein synthesis in patients with glioma of the brain

D. G. T. THOMAS, CATHERINE LANNIGAN and P. O. BEHAN (B. JENNETT), *Department of Neurosurgery, Institute of Neurological Sciences, Glasgow*

Tumour-specific antigens have been demonstrated in glioma of the brain and there is evidence that patients can mount an immunological response to them (Wahlström et al., 1974); however, the prognosis of the condition is poor.

A study was made of lymphocyte protein synthesis in response to graded concentrations of phytohaemagglutinin (PHA) in short term, whole blood cultures (Pauly et al., 1973) of 9 patients with glioma of the brain and 8 with benign intracranial tumours (3 acoustic schwannöma, 5 meningioma). Forty-nine normal subjects and 5 patients with disseminated neoplasia were also studied.

The stimulation ratio of tritiated leucine incorporation in cultures of patients with glioma is significantly depressed, as in those with disseminated neoplasia, but not in patients with benign intracranial tumours. This impairment of cell-mediated immunity may have important implications for management of patients with intracranial tumour.

PHA concentration (μg/ml)	Normal subjects ($n = 49$)	Benign intracranial tumour ($n = 8$)	Glioma ($n = 9$)	Disseminated neoplasia ($n = 5$)
0·26	1·40 ± 0·04	1·33 ± 0·07 NS	1·21 ± 0·09 NS	0·94 ± 0·03 $P<0·01$
1·04	1·79 ± 0·06	1·62 ± 0·09 NS	1·42 ± 0·11 $P<0·05$	0·98 ± 0·06 $P<0·01$
2·08	2·00 ± 0·07	1·72 ± 0·12 NS	1·52 ± 0·13 $P<0·01$	1·00 ± 0·09 $P<0·001$
8·33	2·10 ± 0·07	1·83 ± 0·14 NS	1·45 ± 0·12 $P<0·001$	1·09 ± 0·11 $P<0·001$

All the results given as the mean stimulation ratio ± s.e.m. *P* value on *t*-test. NS, Not significant.

12. Changes induced in bile by female sex hormone

J. A. LYNN and L. F. WILLIAMS jun. (S. J. KARRAN), *Department of Surgery, Boston University Medical Center, Boston University School of Medicine, Boston, Mass.*

The increased incidence of gallstones in young women on the oral contraceptive pill suggests a role of female sex hormones in the formation of lithogenic bile. We studied the effect on hepatic bile flow and composition in 4 Rhesus monkeys with an intact enterohepatic circulation (Lynn et al., 1973) of oestrone and progesterone in daily doses of 0·01 and 0·1 mg/kg of body weight respectively for 7 days.

Oestrone produced a 26·2 per cent mean reduction in bile volume ($P<0·01$). Bile salt secretion fell from a mean of 6·680 to 5·520 mmol/24 hours ($P<0·05$). Cholesterol secretion increased from a mean of 0·115 to 0·225 mmol/24 hours ($P<0·05$). Phospholipid secretion fell from a mean of 0·980 to 0·897 mmol/24 hours ($P>0·1$, not significant). The mean bile salt pool fell from 1·33 mmol to 1·05 ($P<0·02$). The lithogenic index of hepatic bile increased from a mean of 0·38 to 1·2 ($P<0·005$). Progesterone caused no significant change in bile flow or composition ($P>0·1$). Oestrone produced bile supersaturated with cholesterol because of increased cholesterol secretion associated with decreased bile salt secretion due to a diminished bile salt pool.

These studies suggest that the production of lithogenic bile by oral contraceptives is due primarily to their oestrogen content.

LYNN J. A., WILLIAMS L., O'BRIEN J., WITTENBERG J. and EGDAHL R. H. (1973) Effects of estrogens upon bile: implications with respect to gallstone formation. *Ann. Surg.* **178**, 514–522.

13. Low dose heparin prophylaxis against fatal pulmonary embolism

V. V. KAKKAR and T. P. CORRIGAN, *Department of Surgery, King's College Hospital Medical School, London*

Several controlled trials have shown that low dose heparin is effective in reducing the incidence of deep vein thrombosis without increasing the risk of bleeding. However, its effectiveness in preventing fatal pulmonary embolism has yet to be determined, and therefore a multicentre trial was organized in which 31 centres took part. Patients over the age of 40 undergoing only major elective abdominal, thoracic or orthopaedic surgery were included. They were randomly allocated to a control or heparin group and, for each patient entered in the trial, essential information was recorded on a pro forma designed for computer analysis. The incidence of fatal pulmonary embolism was determined by autopsy examination. Altogether 4121 patients were admitted to the trial, 2076 in the control group and 2045 in the heparin group. Sixteen patients in the control group died of acute massive pulmonary embolism which was confirmed at autopsy, but only 2 in the heparin group. The difference is statistically significant (*P* < 0·01). There was no evidence of excessive blood loss during or after surgery.

Low dose heparin prophylaxis can now be recommended as the method of choice for preventing postoperative fatal pulmonary embolism.

14. A simple test for screening surgical patients likely to develop postoperative venous thrombo-embolism

S. SAGAR, D. P. THOMAS and V. V. KAKKAR, *Department of Surgery, King's College Hospital Medical School, London*

A simple and rapid test which could be used preoperatively to select patients who are likely to develop venous thromboembolic complications following surgery would be of great help in deciding which patients require 'active' prophylaxis. During blood clotting, thrombin is produced from its precursor, prothrombin, by the action of activated Factor X in the presence of a lipid and calcium ions. Thrombin thus formed initiates the development of a fibrin clot. Yin and Wessler (1969) have demonstrated the presence of a naturally occurring inhibitor of activated Factor X (XaI) in human plasma.

Factor XaI levels were measured in 25 patients undergoing total hip replacement. Blood samples were taken, for determining Factor XaI levels, before, during and for 5 days after operation. ^{125}I-fibrinogen was used to detect the presence of deep vein thrombosis (DVT). Ten (40 per cent) of the 25 patients developed DVT and in these patients the mean preoperative level of Factor XaI was 73·5 ± 6·9 (s.e.m.) per cent. In the patients who did not develop DVT the mean preoperative level was 101·5 ± 4·3 per cent (*P* < 0·01).

Low levels of Factor XaI in the immediate preoperative period correlate well with the subsequent development of thrombosis in these patients.

YIN E. T. and WESSLER S. (1969) Evidence for a naturally-occurring plasma inhibitor of activated Factor X: its isolation and partial purification. *Thromb. Diath. Haemorrh.* **21**, 398–401.

15. The effect of subcutaneous heparin and operation on antithrombin-III

A. N. NICOLAIDES, I. GORDON-SMITH, F. ZUBAIRI, R. BOWERS and R. C. G. RUSSELL, *Surgical Unit, St Mary's Hospital, London*

Small doses of heparin may prevent deep vein thrombosis by potentiating antithrombin-III (A-III), an inhibitor of activated Factor X (Yin and Wessler, 1970). A-III is consumed during clotting. We have determined the effect of operation and heparin on the blood levels of antithrombin-III.

Fifty patients undergoing general surgical operations were randomly allocated into a test group or a control group. The former received 5000 u. of subcutaneous heparin 2 hours before operation and 12-hourly for 8 days; the latter received subcutaneous saline. Plasma levels of A-III and of heparin were estimated before operation, 2, 4 and 6 hours after the subcutaneous injection on the day of operation and thereafter on the first, third and sixth postoperative days immediately before the morning injection.

In the control group A-III (mean preoperative level 28·54 ± 4·48 mg/100 ml) decreased progressively during and after operation; the reduction was statistically significant on the third postoperative day (25·49 ± 4·80 mg/100 ml; paired *t*-test, *P* < 0·025). The fall of A-III was faster in the heparin group (preoperative level 29·59 ± 4·43 mg/100 ml); significance was reached at 4 hours (26·03) ± 5·01 mg/100 ml; *P* < 0·0125). At 6 hours the fall of A-III in the test group was three times greater than the fall in the control group. There was no relation between plasma levels of heparin and the changes in A-III.

The results suggest that postoperatively heparin causes more A-III to be utilized.

YIN E. T. and WESSLER S. (1970) Heparin-accelerated inhibition of activated Factor X by its natural inhibitor. *Biochem. Biophys. Acta* **201**, 387–390.

16. Reversed segments after massive intestinal resection. Is transit delay hormone-mediated?

A. A. B. BARROS D'SA, T. L. KENNEDY, T. G. PARKS and K. D. BUCHANAN, *Departments of Surgery and Medicine, Queen's University and Royal Victoria Hospital, Belfast*

Hypermotility and rapid transit time are distinctive features of massive intestinal resection. In previous communications to the Surgical Research Society we showed that 75 per cent distal intestinal resection in dogs caused accelerated mouth to caecum transit which was slowed by reversal of the terminal 10 cm of the remnant (*P* < 0·001). We also demonstrated that after such resections plasma gastrin levels rose and levels of total glucagon-like immunoreactivity (GLI) fell (*P* < 0·05). It was suggested that these hormonal alterations were relevant to the mechanisms producing rapid transit.

In this study basal and stimulated levels of several circulating gastro-intestinal hormones were investigated after 75 per cent resection and 10-cm segmental reversal. Radio-immunoassay techniques were employed to measure gastrin, secretin, insulin, pancreatic glucagon and total GLI.

Gastrin levels were significantly lower in this group than in unoperated animals (*P* < 0·001) or after massive resection without reversal (*P* < 0·001). Total GLI levels in the reversal group were significantly higher than those after resection alone (*P* < 0·005).

Thus, resection was associated with accelerated transit, raised gastrin and lowered total GLI levels. Conversely, resection with reversal produced delayed transit, low gastrin and normal total GLI levels.

It is suggested that mechanical stasis produced by reversed segments after massive intestinal resection provokes specific humoral changes which mediate in delayed transit.

17. Respiratory function after oesophageal resection

J. BLACK, G. J. KALLOOR and J. LEIGH COLLIS, *Queen Elizabeth Hospital, Birmingham*

Respiratory function has been studied in 32 patients having oesophageal resection to compare the effects of two standard surgical approaches: 18 patients had a left thoracolaparotomy and 14 a laparotomy and separate right thoracotomy. The groups were similar in age, sex, chest symptoms and smoking habits. The double incision group were transfused slightly less blood but the operation took on average 8 minutes longer.

Arterial P_{O_2} was determined preoperatively and on the first and third postoperative days. Spirometry was done preoperatively and on the thirteenth postoperative day.

Preoperatively there was no significant difference between the groups in these parameters. On the first postoperative day both groups showed a pronounced fall in arterial P_{O_2} with a partial recovery on the third day. This recovery was greater in the double incision group and the difference was significant ($t = 2{\cdot}6$, $P < 0{\cdot}02$). Vital capacity and 1-second expiratory volume were reduced on the thirteenth day in both groups but without significant difference between the groups.

It is concluded that the double incision laparotomy and right thoracotomy approach affects respiratory function less than left thoracolaparotomy. When technically feasible it may be preferable in patients with respiratory impairment.

18. Action of a sterculia bulk-forming agent and smooth muscle relaxant versus bran in diverticular disease

G. SRIVASTAVA, A. N. SMITH and N. PAINTER, *Department of Clinical Surgery, University of Edinburgh and Manor House Hospital, London*

Cereal fibre has effects which are advantageous in diverticular disease: it lowers the colonic intraluminal pressure response to food and to prostigmine (Kirwan et al., 1974). In contrast, the sterculia bulk-forming agent Normacol given for 1 month to 10 patients with diverticular disease increased the pressure in the colon most significantly (motility index $+304 \pm 102{\cdot}5$, $P < 0{\cdot}01$) in response to food. The rise in pressure may follow precipitate movements of colon contents into the sigmoid colon after eating. The reduction in intestinal transit was from 90 to 70 hours (not significant), whereas after bran the reduction was to less than 40 hours ($P < 0{\cdot}01$). When Normacol was combined with a smooth muscle relaxant (alverine citrate), the basal, food-elicited and prostigmine pressures fell sharply (food $276 \pm 101{\cdot}5$; prostigmine 1209 ± 266), i.e. to the same levels as follow the consumption of bran (Kirwan et al., 1974).

The sterculia bulk former Normacol was as effective as bran in relieving 'painful' diverticular disease in a scored randomized clinical trial only if the smooth muscle relaxant was added (the bulk-forming agent alone relieved only the associated constipation). It is postulated that part of the mode of action of bran may be to relax the smooth muscle of the gut, since its actions compare more favourably with sterculia plus a smooth muscle relaxant than with a sterculia preparation alone.

KIRWAN W. O., SMITH A. N., MCCONNELL A. A., MITCHELL W. D. and EASTWOOD M. A. (1974) Action of different bran preparations on colonic function. *Br. Med. J.* **4**, 187–189.

19. A model for studying auto-allergy induced by cryosurgery

A. J. COOPER, J. D. FRASER and JANET IRVINE, *Surgical Division, Southampton University Medical School*

Cryosurgical remnants are potentially immunogenic. Whether such responses can be harnessed for therapeutic ends or whether they may constitute a threat of auto-allergy was investigated by examining the immunological status of guinea-pigs following cryosurgical treatment of one thymic lobe.

At 2–4 weeks after surgery animals were skin tested with 10^6 bone marrow cells, thymocytes and leukaemic (L2C) B lymphocytes. Reactions were read at 24 hours; serum and lymphoid cell suspensions were then prepared from them for *in vitro* cytotoxic assays, and their spleen weight indices were measured. Alternatively, syngeneic guinea-pigs were challenged with L2C tumour immediately after surgery.

Partial cryothymectomy caused significant splenomegaly against all of three control regimens, and reduced the median survival time following challenge with L2C tumour. Skin reactions were positive with thymocytes (6 mm mean diameter), bone marrow cells (9 mm) and L2C cells (10 mm) against a background of < 2 mm normal lymphocyte transfer reaction in control groups. However, ^{51}Cr release assays for cell- and antibody-mediated lysis of thymocytes and L2C cells were negative (< 2 per cent specific release) in all the groups.

These results demonstrate altered immunological responsiveness following cryosurgery which extend beyond reactivity against thymocyte-specific antigens.

20. The effect of surgery on the resistance of guinea-pigs to a transplantable tumour: a possible immunological explanation

A. R. TURNBULL, A. J. COOPER and JANET IRVINE (J. D. FRASER), *Surgical Division, Southampton University Medical School*

An animal model previously described (Cooper et al., 1974) has been used to study the effect of cholecystectomy on the survival of guinea-pigs after injection of a lethal dose of L2C leukaemic cells.

Surgery 6 days before the injection of tumour prolonged the mean survival time by 77 per cent ($P < 0{\cdot}01$) relative to that of the controls. Surgery 1 day after the tumour dose did not significantly affect the survival, but surgery 9 days after the tumour injection shortened the survival time by 35 per cent ($P < 0{\cdot}01$) compared with that of the control animals.

The possibility that this is an immunological phenomenon has been investigated. *In vitro* assays demonstrate at least two cytotoxic mechanisms which may promote or retard tumour growth. Comparative studies investigating the secondary response after challenge with sheep red blood cells show a similar variation. Surgery 7 days before challenge showed a response similar to that of the controls, but for 3 days before challenge the response was increased by 45 per cent. Surgery on the same day reduced the response by 59 per cent ($P < 0{\cdot}01$), and surgery 7 days after by 70 per cent ($P < 0{\cdot}01$).

In the clinical situation impairment of immunological responsiveness following surgery in cancer patients could alter the tumour–host relationship and enhance malignant growth potential.

COOPER A. J., IRVINE J. M. and TURNBULL A. R. (1974) Depression of immunological responses due to surgery. *Immunology* **27**, 393–399.

21. Acquired unresponsiveness to a Gross virus-induced lymphoma in W/Fu rats: evidence for both cellular and humoral suppressor mechanisms

J. A. MYBURGH and N. A. MITCHISON (D. J. DU PLESSIS), *Department of Surgery, University of the Witwatersrand Medical School, Johannesburg, and ICRF Tumour Immunology Unit, University College London*

The purpose of this study was the assessment of induction of tolerance to a highly immunogenic syngeneic Gross virus-induced lymphoma (C58NT)D in W/Fu rats, and an examination of the mechanisms involved in the production of specific unresponsiveness.

Rats were inoculated intraperitoneally within 24 hours of birth with the virus in the form of AKR mouse thymocytes and challenged subcutaneously with tumour 5 weeks later. In contrast to rats challenged primarily at 5 weeks (Shellam, 1974), these animals showed progressive tumour growth and failed to mount an appropriate *in vitro* cell-mediated immune response (CMI) to the tumour. In adoptive transfer experiments to sublethally irradiated (800 rad) syngeneic recipients, spleen cells from these 'tolerant' rats produced enhanced progressive tumour growth, and also abrogated the host protective effect of admixed tumour immune cells. This suppressor effect of 'tolerant' cells was abolished by prior irradiation (2000 rad) of the cells. *In vitro* studies with a ^{51}Cr-release lymphocytotoxicity assay showed similar effects. Suppressor effects *in vitro* were abolished by trypsinization of the cells. A blocking humoral factor, apparently active at target cell level, was also demonstrated in both *in vitro* and *in vivo* assays. It is concluded that acquired tolerance to an immunogenic virus-induced tumour in W/Fu rats can be produced by neonatal exposure to the virus, and that active mechanisms, involving both suppressor cells and humoral factors, are responsible for this state of acquired immunological unresponsiveness to the tumours.

22. Comparison of fructose and glucose clearance during and after major surgery in man

D. O'B. MCCARTHY, P. D. WRIGHT and I. D. A. JOHNSTON, *Department of Surgery, University of Newcastle upon Tyne*

Fasting blood glucose is elevated and the rate of disappearance of infused glucose is reduced after major injury (Wright et al., 1974. Increased insulin antagonism is considered to play a part in post-traumatic glucose intolerance. Fructose metabolism is partly independent of insulin, but there is little information on the effect of injury on the metabolism of fructose by the body.

A study was planned to compare glucose and fructose clearance in two groups of 6 carefully matched male patients who had no metabolic diseases before and after major vascular surgical operations of the same severity. Fructose or glucose (25 g) was given intravenously over a 2-minute period before, during and at intervals for 8 days after surgery.

The rate of clearance of fructose was increased significantly during operation ($P<0{\cdot}01$), but had returned to preoperative levels by the first postoperative day. Glucose clearance, in contrast, was reduced during and throughout the 8 days of the study.

The fructose load produced a brisk insulin response before operation. This response was diminished and delayed during surgery. These findings suggest that fructose might be utilized as a calorie source more efficiently than glucose during and immediately after surgical operation.

WRIGHT P. D., HENDERSON K. and JOHNSTON I. D. A. (1974) Glucose utilization and insulin secretion during surgery in man. *Br. J. Surg.* **61**, 5–8.

23. The modification of the adaptive response to stress by carbohydrate-containing infusions

B. J. ROWLANDS, A. E. B. GIDDINGS and R. G. CLARK, *University Surgical Unit, Northern General Hospital, Sheffield, and Royal Devon and Exeter Hospital, Wonford, Exeter*

Insulin resistance is associated with simultaneous elevations of glucose and non-esterified fatty acids (NEFA) to satisfy postoperative energy requirements (Giddings, 1974). These changes may be modified by carbohydrate and amino acid infusions.

Basal plasma values±s.e.m. in 34 patients studied were as follows:

	Preoperative	Postoperative	*P* value
Glucose (mmol/l)	5·14±0·118	6·60±0·191	<0·001
NEFA (μmol/l)	103·1±5·11	119·6<4·31	<0·005

In 18 patients a 2-hour infusion of glucose, fructose or sorbitol (0·5 g/kg of body weight h^{-1}) produced significant falls in NEFA ($P<0{\cdot}001$, $<0{\cdot}005$ and $<0{\cdot}01$ respectively). Postoperatively these changes were associated with hyperglycaemia ($P<0{\cdot}005$) and rises in immunoreactive insulin ($P<0{\cdot}001$). Similar changes were observed in 4 patients receiving a 5-hour infusion of fructose and in 6 patients receiving a 2-hour infusion of L-amino acid 70 g/l and fructose 100 g/l.

Six patients received a provocative arginine infusion test (12 mg/kg of body weight min^{-1}). Preoperatively there was elevation of plasma glucose ($P<0{\cdot}001$) and a fall in NEFA ($P<0{\cdot}01$). Postoperatively there was no change in glucose and an insignificant fall in NEFA. The insulin response was similar in each test.

Infusions which contain carbohydrate alter the adaptive response to stress by reducing NEFA, but arginine maintains high levels of both NEFA and glucose. Amino acid infusions alone may thus have advantages over conventional nutritional regimens in stress situations.

GIDDINGS A. E. B. (1974) The control of plasma glucose in the surgical patient. *Br. J. Surg.* **61**, 787–792.

24. Comparison of highly selective vagotomy (HSV) plus dilatation and of vagotomy with a drainage procedure (V+D) in the treatment of pyloric stenosis secondary to duodenal ulceration

M. J. MCMAHON, M. J. GREENALL, D. JOHNSTON and J. C. GOLIGHER, *University Department of Surgery, The General Infirmary, Leeds*

The hypothesis that patients with pyloric stenosis would obtain better clinical results after HSV plus dilatation of the stenosis than after V+D (Johnston et al., 1973) was tested by 'blind' review of two groups of patients at a follow-up clinic: 23 consecutive patients who had undergone HSV for pyloric stenosis were compared with a series of 23 patients treated by V+D for pyloric stenosis by another surgeon. The length of follow-up was the same (0–4 years) and the two groups were similar with respect to age, sex, weight, maximum acid output and length of ulcer history.

	HSV	V+D
Operative mortality	0	0
Reoperation for stasis	2	1
Recurrent ulceration	0	0
Perfect result (Visick grade 1)	75%	45%
Good result (Visick grades 1+2)	95%	75%
Early dumping	10%	10%
Diarrhoea	5%	20%
Vomiting	10%	14%
Flatulence	10%	23%
Epigastric fullness	15%	32%

The results demonstrate the remarkable propulsive powers of the hypertrophied gastric antrum in pyloric stenosis: re-stenosis occurred in only 2 patients after HSV who did well after gastric drainage. Patients had a much better chance of obtaining a perfect result, without side effects, after HSV than after V+D. These findings support the hypothesis, which should be tested further in a prospective random trial.

25. Multivariate analysis of clinical and operative findings associated with biliary sepsis

M. R. B. KEIGHLEY, A. R. CRAPP, R. FLINN and J. ALEXANDER-WILLIAMS, *The General Hospital, Birmingham*

Operations for biliary disease are associated with a high incidence of wound sepsis (Report, 1960) and septicaemia, particularly in jaundiced patients (Flemma et al., 1967). Biliary micro-organisms are responsible for these complications, and prophylactic antibiotics will minimize this morbidity (Bevan and Williams, 1971). Effective prophylaxis depends upon satisfactory tissue antibiotic concentrations at the time of bacterial contamination (Burke, 1961).

To identify patients with biliary micro-organisms and hence avoid indiscrimant use of prophylactic antibiotics, a multifactorial analysis of clinical and operative findings has been obtained from a prospective study of patients requiring biliary surgery; none had been given preoperative antibiotics ($n=181$).

Cluster analysis of 17 preoperative and 11 operative variables defined a high risk ($n=45$) and a low risk ($n=136$) population, where the incidence of biliary sepsis was 67 and 15 per cent respectively ($P<0{\cdot}001$). Seven findings were much more common in the high risk than in the low risk group ($P<0{\cdot}001$). These 'high risk factors' were: jaundice at operation, recent rigors, emergency surgery, age over 70 years, previous biliary surgery, common duct obstruction and stones in the bile duct. In 57 patients where one or more of these 'factors' was present the bile was infected in 34 (60 per cent). When

4 'high risk factors' occurred in the same patient (20 cases) biliary organisms were isolated in 19 (95 per cent).

We conclude that the presence of one or more 'high risk factors' indicates a group in whom prophylactic chemotherapy would be advised.

26. The effect of noxytiolin (Noxyflex) in peritonitis due to perforated appendicitis

D. W. KING, J. F. GURRY, R. B. ELLIS-PEGLER and B. N. BROOKE, *Department of Surgery, St George's Hospital Medical School, London*

The evidence for the value of noxytiolin in peritonitis is contradictory. Intraperitoneal injection of noxytiolin has been shown to offer significant protection against a lethal Gram-negative peritonitis in guinea-pigs, and these results have been thought to account in part for a low mortality rate in a series of patients with faecal peritonitis (Browne and Stoller, 1970). Other workers were unable to show that lavage with noxytiolin was more beneficial than with Hartmann's solution in faecal peritonitis in rats (Cleaver et al., 1970).

A rabbit model of perforated appendicitis similar pathologically and bacteriologically to the condition in humans has been used in a controlled trial of peritoneal instillation of noxytiolin. There was a 17·6 per cent mortality in the control group and 55·6 per cent mortality in the trial group ($P<0{\cdot}05$). A greater postoperative weight loss was seen in the trial group compared with that of the controls ($P<0{\cdot}01$).

In a double blind clinical trial of 27 patients with perforated appendicitis there was no significant difference in wound infection rate, length of stay in hospital or other complications between a placebo control group and a group treated with intraperitoneal noxytiolin solution at the time of operation.

27. Collagen metabolism in infected colonic anastomoses

T. T. IRVIN, *University Department of Surgery, Royal Infirmary, Sheffield*

It is alleged that colonic anastomoses fail in the presence of infection due to increased tissue collagenolysis (Hawley, 1973). However, there have been no detailed studies of collagen metabolism in infected anastomoses.

Twenty-five male Sprague–Dawley rats were labelled with 5-^{3}H-L-proline for 6 weeks before collagen metabolism was studied in normal and infected anastomoses in the left colon. The anastomoses were removed 3 or 7 days after surgery, and the hydroxyproline content and radioactivity (DPM) in the salt-soluble (SSC), acid-soluble and insoluble (ISC) collagen fractions were measured (Prockop et al., 1961).

Anastomoses on days 3 and 7 were compared with control values in anastomoses removed from the same animals on the day of surgery. On day 3 there was a 23–25 per cent reduction in ISC, and a 30 per cent reduction in DPM of ISC in normal and infected anastomoses. SSC in normal anastomoses increased by 82 per cent, but there was a 32 per cent reduction in infected anastomoses (Wilcoxon test, $P<0{\cdot}01$). Similar differences in DPM were found in SSC ($P<0{\cdot}005$). On day 7 the size of all the collagen fractions was increased, and there was a small increase in DPM. There was no significant difference between normal and infected anastomoses.

The results are compatible with the thesis that infection causes increased collagenolysis, but they could also be explained by a reduction in colonic collagen synthesis.

28. Effects of gastric surgery on differential emptying of solid and liquid components of the gastric contents

R. C. HEADING, P. TOTHILL, G. P. MCLOUGHLIN and D. J. C. SHEARMAN (D. C. CARTER), *Gastrointestinal Section, Department of Therapeutics and Department of Medical Physics, University of Edinburgh*

Following a natural meal the solid and liquid components of the gastric contents are believed to empty through the pylorus at different rates (Hunt and Knox, 1968). Using a scintiscanning method with double isotope labelling of a meal (Heading et al., 1974), we have studied the effects of gastric surgery on emptying rates of the two components. Measurements were performed during the period 35–120 minutes after ingestion of a meal, so that emptying involving mechanisms particular to the early phase was excluded.

In 18 control patients given a meal of cornflakes, sugar and milk the solid marker emptied more slowly than the liquid marker ($P<0{\cdot}01$). In 19 patients with duodenal ulcer, 13 patients with highly selective vagotomy and 14 with truncal vagotomy and pyloroplasty (Heineke-Mikulicz) mean emptying rates of both markers were slower than in the controls, but the relationship between them was maintained. However, in 6 patients with Billroth II gastrectomy solid emptying was faster, though liquid emptying was slower than in the controls, the relationship being significantly altered ($P<0{\cdot}01$).

The results suggest that differential emptying of the solid and liquid components of the gastric contents is effected by the gastric antrum, is largely independent of the actual emptying rate and is unaltered by pyloroplasty.

29. The effect of carbenoxolone and phenol red on the permeability of steroid-treated gastric mucosa, using ^{99}Tc as a tracer

B. M. NEWMAN, J. B. ELDER and I. E. GILLESPIE, *University Department of Surgery, Royal Infirmary, Manchester*

Carbenoxolone and phenol red are known to alter gastric mucosal function. The effects of these substances alone and in combination with prednisolone on the gastric mucosa of 64 rabbits, using ^{99}Tc as a tracer, have been studied on mucosal flaps using an *in vivo* chamber.

Oral carbenoxolone 15 mg and 50 mg daily for 7 days caused a significant decrease in flux of ^{99}Tc from the lumen in both the antrum ($P<0{\cdot}001$) and the fundus ($P<0{\cdot}001$). When 1 ml of a solution of phenol red (25 mg/l) was placed on the mucosa a similar decrease in flux was noted ($P<0{\cdot}001$).

Prednisolone 10 mg daily for 7 days increased the antral but not the fundic flux of ^{99}Tc. This selective antral effect was significantly reduced by combining 50 mg/day carbenoxolone with prednisolone over the period of study. The addition of phenol red to the chamber in steroid-treated animals decreased the mucosal ^{99}Tc flux significantly below control values ($P<0{\cdot}001$).

This work suggests that carbenoxolone and phenol red may have a 'protective' effect on steroid-treated gastric mucosa.

30. The effect of portal and systemic venous drainage of the pancreas on glucose and insulin metabolism

J. COLLIN, R. M. R. TAYLOR and I. D. A. JOHNSTON, *Department of Surgery, University of Newcastle upon Tyne*

Persistent hyperinsulinaemia and hypoglycaemia have been reported (Lillehei et al., 1970) after heterotopic pancreatic transplantation and has been attributed to diversion of pancreatic vein blood from the portal vein (Sells et al., 1972). Experiments were designed to examine this hypothesis.

Group I comprised 8 dogs in which all pancreatic tissue was excised other than the pancreatic tail which continued to drain into the portal vein. Intravenous glucose tolerance tests revealed normal glucose clearance on the first postoperative day with an increased insulin response (mean 60·9 μu./ml, $P<0{\cdot}05$), while on the fourth and twenty-second postoperative days glucose clearance was reduced ($P<0{\cdot}005$) and the insulin response was diminished (mean 14 μu./ml, $P<0{\cdot}05$).

In group II, 14 totally pancreatectomized dogs had a heterotopically autotransplanted pancreatic tail, the venous drainage being to the iliac veins. Fasting hyperinsulinaemia was present on the second postoperative day ($P<0{\cdot}025$), but hypoglycaemia did not occur. The insulin response to glucose was increased on the first postoperative day (mean 69·4 μu./ml, $P<0{\cdot}025$) but decreased subsequently (mean 20·9 μu./ml, $P<0{\cdot}05$). Glucose clearance was normal on the first postoperative day, but was subsequently decreased on the twenty-second postoperative day ($P<0{\cdot}05$). Comparisons of glucose clearance, insulin response, fasting insulin and glucose levels revealed no significant differences between the groups.

It is concluded that there is no demonstrable advantage to glucose homeostasis from portal as opposed to systemic venous drainage of the pancreas.

31. Changes in volume of the breast during the menstrual cycle

T. HAMILTON and MARY E. RANKIN, *Department of Clinical Surgery, University of Edinburgh*

Perhaps the difficulty in achieving reproducible measurements accounts for the paucity of information on the nature of changes in breast volume which, as every women appreciates, takes place during the menstrual cycle. A simple apparatus has been devised by which the volume of both breasts can be measured by their immersion in water through a rectangular orifice in a plywood board placed over a suitable container. The displaced water is collected via a side channel conduit. By accurately replacing sites of contact at both inframammary sulci, shoulders and sternal notch, reproducibility to within ±6 per cent has been obtained.

Daily measurements have been done together with daily temperature recordings and weekly oestrogen and progesterone levels to determine the time of ovulation. In normal women volume increases of between 30 and 40 per cent have been obtained, the increase beginning at ovulation, reaching a peak 24–48 hours before the onset of menstruation and returning to the baseline by the end of menstruation. Studies to assess the possible effects of the contraceptive pill are in progress.

32. Synthesis of oestradiol by human breast cancer

W. R. MILLER and A. P. M. FORREST, *Department of Clinical Surgery, University of Edinburgh*

Thirteen human breast cancers have been studied with regard to their ability to synthesize oestradiol-17β from the C19 steroid testosterone. Slices of each tumour were incubated *in vitro* with 7α(^{3}H)-testosterone for 2 hours at 37 °C.

The conversion of testosterone to oestradiol-17β was determined by measuring the incorporation of the radioactive label into oestradiol after purification by thin layer chromatography and characterization by chemical derivative formation. Simultaneous estimates were carried out to characterize C19 steroid metabolites.

All the tumours metabolized significant amounts of testosterone (20–50 per cent), and in 6 unequivocal evidence for the synthesis of significant amounts of oestradiol was obtained. In 2 tumours conversions were 0·22 and 0·37 per cent, but in 4 smaller amounts (0·04–0·07 per cent) were produced.

As previously described with other breast tumours (Miller et al., 1973), all the tumours metabolized testosterone to Δ4-androstenedione, 5α-dihydrotestosterone and 5α-androstanediol.

The synthesis at tumour level of active oestrogen from precursor C19 (androgenic) steroids may be of prime importance in determining the nature of hormone dependence.

MILLER W. R., MCDONALD D., FORREST A. P. M. and SHIVAS A. A. (1973) Metabolism of androgens by human breast tissue. *Lancet* **1**, 912–913.

33. Clinical correlates of cell-mediated reactivity to autologous tumour antigens in breast cancer

A. R. TURNBULL and B. M. JONES (J. D. FRASER), *Surgical Division, Southampton University Medical School, and Tenovus Research Laboratories, Velindre Hospital, Cardiff*

The leucocyte migration inhibition test (Søborg and Bendixen, 1967), an *in vitro* test of cell-mediated immunity, has been performed serially on patients with breast cancer. The patients form part of an on-going clinical trial comparing simple mastectomy alone with simple mastectomy plus radical radiotherapy for operable breast cancer (clinical stages I and II). An axillary lymph node biopsy was routinely performed at operation.

At 2 months there was a significant difference in reactivity between lymph node positive (11 out of 38) and lymph node negative patients (3 out of 37; $P=0{\cdot}05$). Comparison between the observed and irradiated groups at 6 months showed that 8 out of 24 (33 per cent) of the treated patients were positive but none of the 18 patients in the watched group reacted ($P=0{\cdot}05$). At 7 days, 2 months and 12 months there was no significant difference between these groups.

No significant correlation could be demonstrated between reactivity in the leucocyte migration test and reactivity *in vivo* as shown by histological examination of the tumours and lymph nodes and by skin testing.

These results suggest that residual tumour might maintain sensitivity after removal of the primary antigenic stimulus. Similarly, irradiation may cause disruption of nodal metastases with release of circulating antigenic fragments which produce positive reactions apparent at 6 months.

SØBORG M. and BENDIXEN G. (1967) Human lymphocyte migration as a parameter of hypersensitivity. *Acta Med. Scand.* **181**, 247–256.

34. The immune reaction to human breast cancer tissue

M. MAUREEN ROBERTS and ELEANOR M. BASS, *Department of Clinical Surgery, University of Edinburgh*

A study is in progress to determine the incidence of immune reactivity in patients with primary breast cancer towards their own tumours, and to correlate the findings with clinical prognosis.

Extracts of autologous tumours standardized for protein content have been used throughout in tests of both cellular and humoral immunity with the following results:

1. Cellular immunity: Strong positive reactions to tumour extract were observed in 7 of 37 patients by skin testing and in 11 of 40 patients by the leucocyte migration inhibition test; serum blocking factors were found in only 7·5 per cent.

2. Humoral immunity: Serum antibodies to tumour were found in 4 of 60 patients tested by Ouchterlony analysis and 2 of 40 patients by the complement fixation test; serum IgA was raised and the relative levels of immunoglobulins in breast cancer tissue were altered compared with those in normal breast tissue, with high levels of IgM in some and abnormal IgG in others when estimated by immunodiffusion and demonstrated by immunofluorescent techniques.

We conclude that by the methods used approximately 20 per cent of patients at the time of mastectomy have a strong cellular immune reaction to their own tumours. The incidence of circulating antibodies is low, but interesting abnormalities may exist at tissue level.

35. The leucocyte migration inhibition test in cancer immunology

P. R. ARMITSTEAD, G. GOWLAND and G. R. GILES, *University Department of Surgery, St James's Hospital, and University Department of Immunology, The General Infirmary, Leeds*

The leucocyte migration test is used as a test of cell-mediated immunity against cancer. However, the test lacks sensitivity and produces results which are difficult to interpret.

We have attempted to explain some of the inconsistencies by using the separated mononuclear and granulocyte fractions in 10 per cent homologous AB serum or 10 per cent autologous serum and a colorectal tumour antigen. Normal patterns of migration for each cell fraction were established in homologous AB serum of 6 control subjects. In autologous serum the mononuclear cell fraction migrated normally with tumour antigen, but 3 out of 6 of the tests using the granulocyte fraction and non-separated leucocytes showed apparent migration inhibition.

Nine patients with colorectal cancer were examined. Five showed migration inhibition using non-separated leucocytes in both sera. Significant migration inhibition occurred in all the tests with the mononuclear cell fraction in AB serum. Using the granulocyte fraction, migration inhibition was not seen with AB serum, though two tests were positive in autologous serum.

The study shows increased sensitivity of the migration inhibition tests using a mononuclear cell fraction, and that autologous serum may interfere directly with migration of granulocytes, by an action not dependent upon the release of inhibitory factors from sensitized lymphocytes.

36. Plasma esterolytic activity during acute pancreatitis in the human

A. CUSCHIERI and KAREN J. WORTHINGTON, *Department of Surgery, University of Liverpool*

There has been a renewed interest in the administration of aprotinin (Trasylol) in acute pancreatitis since the favourable report on its use by Trapnell et al. (1974). In the present study plasma esterolytic activity was measured serially in 12 patients with acute pancreatitis, 10 patients with intra-abdominal inflammatory conditions (contrast group) and 7 healthy volunteers. The esterolytic activity was assayed in samples of heparinized plasma using benzoyl arginine ethyl ester with the modified NAD/alcohol dehydrogenase method (Worthington and Cuschieri, 1974). The serum amylase was also measured in patients with acute pancreatitis. *In vitro* inhibition of plasma esterolytic activity was studied using Trasylol, ovomucoid and soybean inhibitor. The results are presented as means ± s.d.

The plasma esterolytic activity in the contrast group was 617·0 ± 385·0 mu./100 ml and this did not differ from the value in the control of 611·0 ± 275·0 mu./100 ml ($P = 0{\cdot}98$). The level of esterolytic activity in acute pancreatitis varied with the duration of the disease:

Duration of pancreatitis (d)	Esterolytic activity (mu./100 ml)	Serum amylase (Somogyi units/100 ml)
0–2	2270 ± 859*	2759 ± 1848
2–4	1755 ± 946*	637 ± 425
4–6	863 ± 409	259 ± 224
6–8	1261 ± 675*	116 ± 20
>8	1235 ± 575*	204 ± 90

* Significant difference from controls ($P < 0{\cdot}01$) using the Wilcoxon rank test.

An 82 ± 24 per cent inhibition was obtained when Trasylol (0·2 ml, 2000 Kallikrein inactivator units) was added to 0·3 ml of plasma from patients with acute pancreatitis. Soybean inhibitor gave a 51 ± 29 per cent inhibition and ovomucoid 34 ± 28 per cent.

It is concluded that a sustained esterolytic activity reflecting the release of proteolytic enzymes occurs in acute pancreatitis. The activity is maximal during the first 4 days of the illness, with a later rise between the sixth and the tenth days. Although Trasylol inhibits this activity, the dose required would need to be much higher than that which has been used clinically.

37. *In vitro* studies on human renal pelvis muscle

N. LONGRIGG (I. E. GILLESPIE), *University Department of Surgery, The Royal Infirmary, Manchester*

The possible role of autonomic nerves in modifying motor activity of the human renal pelvis is as yet unknown.

Isolated strips (10 preparations) of human renal pelvis, obtained at operation, were studied in an organ bath by an isometric technique. Platinum electrodes positioned alongside the tissue provided electrical transmural stimulation.

Preparations responded to adrenaline, noradrenaline and phenylephrine by an increase in tension. This response could be abolished by pretreatment with small doses of phentolamine (160 ng/ml), suggesting that it was mediated by α-adrenoceptors. A similar excitatory response to the addition of acetylcholine could be antagonized by atropine in a concentration of 20 ng/ml, indicating the presence of muscarinic receptors.

An increase in tension after electrical stimulation occurred only when the pulse width was greater than 4 msec (current strength 150 mA, frequency 2–32 Hz). By comparison with other autonomically innervated tissues, such a large pulse width suggests that in renal pelvis muscle the response was *not* caused by nerve depolarization, and most probably represented direct muscle stimulation. This was confirmed by finding that exactly similar qualitative and quantitative responses were obtained before and after treatment of the tissues with tetrodotoxin, a potent neurotoxin which selectively blocks nerve as opposed to muscle depolarization.

These results suggest that the receptor sites identified are not effectively innervated, and that motility of the human renal pelvis is completely independent of the autonomic nervous system.

38. Effective temporary hepatic support in acute liver failure

M. SLAPAK and D. C. WILKINS, *Department of Surgery, University of Cambridge*

A new canine model of acute liver failure has been developed (Slapak and Wilkins, 1975). The purpose of this study was to determine the length of support time needed for otherwise lethal liver damage to recover.

Twelve dogs (group A) had a 2-hour ischaemic interval imposed on two-thirds of their liver (main lobe, ML); the remaining third (supporting lobe, SL) served to decompress the portal circulation and hepatically support the animal. At the end of this period the afferent blood supply to the ischaemic ML was allowed to resume whilst that to the SL was permanently arrested. All 12 dogs temporarily recovered and were ambulant. Coma and death due to ischaemic liver necrosis took place 22 ± 3 hours after resumption of flow. Clinical, biochemical and EEG evidence of acute liver failure as the cause of death was present.

In group B (10 dogs) the blood supply to the ML was normal but the SL was permanently ligated. All the animals survived in good health until sacrifice 3 weeks later. No evidence of liver abnormality was present.

In group C (7 dogs) a 2-hour ischaemic period was imposed on the ML as in group A, but the blood supply to the SL was not arrested. All 7 dogs survived until 10–14 days when the SL was resected. Six of the dogs survived in good health for a further 1 month till sacrifice. At 12 hours after release mean SGPT was 1700 i.u., prothrombin time 24 seconds and BSP retention 24 per cent. These values became normal within 3 days. Delta waves in the EEG also recovered. Histologically, evidence of a recovering pericentral vein necrosis was seen. The study shows that effective liver support for 10–14 days completely reverses an otherwise 100 per cent lethal hepatic injury.

39. Effect of superimposed cold ischaemia on a long warm ischaemic interval

S. ROGERS and M. SLAPAK, *Department of Surgery, University of Cambridge*

Although the mean warm ischaemic interval of cadaveric kidneys transplanted by us in 1974 (62 minutes) has not altered from that in 1968 (64 minutes), the mean cold ischaemic interval has trebled. A study to define the possible accumulative effect of varying cold superimposed on warm anoxia was therefore performed in two groups of rats.

In group A, 35 diuresing kidneys were removed and 45 minutes' ischaemia at 37 °C imposed. Seven kidneys in each of subgroups I–V of group A were then rapidly cooled and stored at 4 °C for 0, 6, 12, 18 and 24 hours respectively. At these times the kidneys were removed and the ability of 0·3-mm slices to take up PAH ^{125}I from a buffer solution was determined—the S : M ratio (Lannon et al., 1971). This was $3{\cdot}1\pm1{\cdot}3$, $2{\cdot}7\pm0{\cdot}4$, $2{\cdot}9\pm0{\cdot}2$, $1{\cdot}9\pm0{\cdot}3$ and $1{\cdot}5\pm0{\cdot}3$ respectively. Values at 0, 6 and 12 hours differed ($P<0{\cdot}001$) from those at 18 and 24 hours. In the control group B warm ischaemia was not imposed. In subgroup VI (12 kidneys) 24 hours' cold ischaemia only was imposed (S : M ratio $2{\cdot}9\pm0{\cdot}4$). In subgroup VII (14 kidneys) no ischaemia of any sort was imposed (S : M ratio $7{\cdot}3\pm0{\cdot}9$).

It has previously been shown (Slapak and Rogers, 1975) that a kidney S : M ratio of less than 2 carried a 25 per cent risk of uraemic death even after a 3-week support period ensured by a delayed contralateral nephrectomy. The data therefore show that, under the experimental conditions imposed, a cold ischaemic interval of longer than 12 hours has a significantly detrimental effect on kidneys already exposed to a 45-minute warm ischaemic interval. Nevertheless, such periods of cold or warm ischaemia alone are well tolerated.

40. The immunosuppressive effect of surgery and its relation to rejection in the immediate postoperative period

R. F. M. WOOD, P. R. F. BELL, AILEEN C. GRAY and S. G. PACKER, *Department of Surgery, University of Leicester, and Department of Pathology, University of Glasgow*

Surgery is known to cause a temporary depression of the immune response (Bancewicz et al., 1973). This study was undertaken to assess the effect of a strong antigenic challenge with an allograft upon this reaction.

Cell-mediated immunity was studied using the leucocyte migration test before and after surgery in two groups of 6 dogs with either autotransplants (group 1) or allotransplants (group 2). The autotransplanted animals were sensitized with *Bordetella pertussis* before surgery and this agent was used to assess their immune response. In the allograft group reactivity was measured in response to donor liver, spleen, lymph node and kidney. In both groups blast cell activity was monitored by the spontaneous uptake of ^{14}C-labelled thymidine by lymphocytes. The blood urea, serum creatinine and immunological tests were performed daily after operation.

In group 1 cell-mediated immunity was impaired for 3 days and then returned to normal. Blast cell activity (^{14}C-labelled thymidine) was, however, impaired for several weeks, showing a small but temporary rise on day 5. In group 2 cell-mediated immunity was increased by the sixth day with significant inhibition of migration. Blast cell activity (^{14}C-labelled thymidine) was again reduced after surgery, and there was a temporary increase between the sixth and ninth postoperative days.

These results suggest that spontaneous blast cell transformation as a non-specific measure of immune activity was depressed after both auto- and allotransplants. However, cell-mediated immunity to a specific antigen is only temporarily affected by operation and the development of sensitization to transplantation antigens occurs despite the fall in blast cell activity.

41. Prognostic significance of circulating inhibitory factors of mixed lymphocyte culture for human renal allograft survival

D. E. OSBORN and J. E. CASTRO, *Urology and Transplant Unit, Royal Postgraduate Medical School, London*

Survival of human renal allografts may be influenced by circulating humoral factors. Patients who underwent cadaver renal transplantations were examined for factors which inhibit mixed lymphocyte culture (MLC), and the results were correlated with graft survival.

Inhibition of MLC was measured in a one way culture by adding 20 per cent of test serum and the results compared with culture containing control AB serum. In each experiment 6 combinations of recipient and unrelated mismatched lymphocytes were studied. Significant inhibition occurred if the ratio of transformation in control and test cultures was at least 2·5.

In the patients with a successful transplant serum taken before operation caused blocking of MLC in 2 of 6 patients and in only 4 of 36 lymphocyte combinations. Serum taken after transplantation caused blocking in 4 of 7 patients and only 4 of 42 combinations.

In patients whose transplanted kidney was rejected, blocking occurred before transplantation in all the patients and in 20 of 36 lymphocyte combinations. Serum taken after transplantation caused blocking in 7 of 8 patients and in 21 of 42 combinations. Four kidneys were removed for non-immunological causes.

These observations suggest that the presence of circulating inhibitory factors of MLC are associated with a significantly increased incidence of transplant rejection.

42. Rat cardiac allograft survival by treatment with promethazine-HCl

S. W. JAMIESON (J. D. LEWIS), *Northwick Park Hospital, Harrow, Middlesex*

In rat cardiac allografts the production of humoral antibody is associated with progressive and irreversible intimal thickening. This process is seen in human transplants and is the main barrier to long term survival of cardiac and renal grafts.

Electron micrographic studies performed on cardiac xenografts between guinea-pigs and rats show that massive intravascular coagulation of platelets and fibrin occurs in response to antibody insult. The graft vascular endothelium is destroyed subsequent to platelet contraction.

Promethazine-HCl (Phenergan) inhibits antibody production (Gusdon et al., 1972) and the second stage of platelet aggregation (Mills and Roberts, 1967). In a control series of 24 cardiac allografts between AgB,AgC compatible rats, 12 were rejected before 20 days (mean rejection time 15 days). Ten showed spontaneous survival, probably as a result of enhancing antibody on the endothelium. Ninety transplants were performed in recipients treated with promethazine-HCl. Continuous treatment resulted in survival of all the grafts and reduction of intimal thickening. Cessation of treatment on day 4 after transplantation had no effect, but treatment continued to day 8 only again produced total survival.

It is suggested that endothelial cell integrity is important for the survival of transplants, because it both reduces lymphocytic infiltration of the graft and subsequent intimal thickening. Promethazine-HCl has the effect of protecting the endothelium from antibody-induced platelet damage when antibody begins to circulate.

43. Experimental revascularization of myocardial infarction

J. N. FABIANI, A. DELOCHE, J. P. CAMILLIERI, D. JOSEPH, M. SCHLUMBERGER, J. RELLAND and A. CARPENTIER, *Laboratoire d'Etudes des Greffes et Prothèses Cardiaques, Institut Biomédical des Cordeliers, Paris*

Histo-enzymatic studies of the myocardium and electron microscopic study of the capillary network have been carried out in order to evaluate the effect of early revascularization of myocardial infarction in the rat.

The histo-enzymatic study was carried out in 56 animals. In 14 the left coronary artery was ligated, creating an extensive transmural anterolateral infarct within the first hour with disappearance of phosphorylase activity at the end of 6 hours; a marginal necrotic zone was identified by succinyl dehydrogenase, the activity of which ceased after 48 hours. In 42 animals ligation of the left coronary artery was temporary, lasting 1 hour (27 cases), 6 hours (12 cases) and 12 hours (3 cases). Enzymatic studies demonstrated a reduction, by half of the size of the infarct, mainly in the marginal zone; this occurred in 75 per cent of the cases when the ligature was released after 1 hour and in 50 per cent of the cases when the ligature was released at the end of 6 hours.

Study of the capillary circulation during infarction was undertaken in 60 animals by measuring coronary perfusion pressure and by performing electron microscopy after the injection of indian ink. Coronary perfusion pressure was found to be significantly increased in ischaemias lasting more than 20 minutes. Electron microscopic study revealed a marked pyknosis of the endothelial cells as well as interstitial oedema, reducing the calibre of the capillaries and favouring sludging of erythrocytes.

We conclude that: (1) histo-enzymatic study permits a more precise mapping of the infarcted area and further documents the reversibility of myocardial infarction following early revascularization; (2) reversibility of infarction is found mainly in the marginal zone of ischaemia and is inconstant; (3) endothelial and subendothelial changes are secondary factors leading to capillary blockage aggravating the primary ischaemic lesion.

44. Interpretation of lower oesophageal pressure measurements

C. PEREZ-AVILA and T. T. IRVIN, *Department of Surgery, Royal Infirmary, Sheffield*

It is claimed that manometric measurements of lower oesophageal sphincter pressure (LESP) provide useful information in the diagnosis of gastro-oesophageal reflux (Ingelfinger, 1971). However, little is known of the day-to-day variation in LESP and the accuracy of such measurements has been questioned (Stef et al., 1974).

The reproducibility of pressure measurements in the lower oesophagus has been studied in patients without symptoms of gastro-oesophageal reflux. Using a water-perfused triple catheter assembly, mean and end-expiratory LESP and gastric and oesophageal pressures were measured, twice on the same day in 26 subjects, and once on separate days in 11 subjects. The pressure response to abdominal compression was recorded and the stomach/oesophageal sphincter pressure gradient or barrier pressure (BP) was calculated.

Sequential measurements on the same day gave reproducible results for LESP ($r = 0{\cdot}89$) and BP ($r = 0{\cdot}91$), and the response of the BP to abdominal compression was also reproducible ($r = 0{\cdot}89$). Studies on different days showed significant variations in LESP ($r = 0{\cdot}37$) and BP ($r = 0{\cdot}13$).

The results suggest that there is a significant day-to-day variation in the tone of the lower oesophageal sphincter, and that manometric studies of the gastro-oesophageal junction should be interpreted with caution.

45. A simple clinical method for measurement of gastric emptying of solid meals

D. G. OSTICK, G. GREEN, K. HOWE, I. W. DYMOCK and D. J. COWLEY, *Departments of Surgery and Medicine, University Hospital of South Manchester, and Department of Biophysics, University of Manchester*

The radio-isotope technique used for the measurement of gastric emptying of solid meals in man requires complex and expensive scintiscanners (Griffiths et al., 1968) or gamma cameras (Jones et al., 1970), which are only available in a few centres. We have evaluated a simpler technique which utilizes a single scintillation detector and have compared the results obtained with those from a gamma camera.

Twenty healthy volunteers ate a standard meal labelled with 500 μCi of ^{99}Tc sulphur colloid. Radioactivity from the stomach was counted simultaneously with (1) a gamma camera with an on-line computer (Hancock et al., 1974) and (2) a single scintillation detector positioned over the area of maximal activity. All the subjects were studied standing.

In each of the 20 subjects the rate of emptying as measured by the two methods correlated closely (mean $r = 0{\cdot}95$, range 0·77–0·99). The mean percentage of activity which remained in the stomach at any time interval after eating was virtually identical for the two techniques. The mean half emptying time ($T_{\frac{1}{2}}$) with the gamma camera was $49{\cdot}3 \pm 19{\cdot}8$ (s.d.) min and with the scintillation detector $48{\cdot}2 \pm 21{\cdot}1$ min.

The single scintillation detector provides a reliable and inexpensive method. It could be used as a simple quantitative test of gastric emptying in patients with gastric disorders.

46. Plasma gastrin after proximal gastric vagotomy and vagotomy and antrectomy

C. M. S. ROYSTON, W. M. COOKE, R. C. G. RUSSELL, S. R. BLOOM and J. SPENCER, *Departments of Surgery and Endocrinology, Royal Postgraduate Medical School, and Surgical Unit, St Mary's Hospital, London*

The effect of proximal gastric vagotomy (PGV) on plasma gastrin is still uncertain; conflicting results have been reported and different techniques used. We have used a standardized insulin-bicarbonate test (Cowley et al., 1973) to study gastrin release before and 10 days and 3 months after operation in 9 patients undergoing PGV and in 12 undergoing vagotomy and antrectomy (TVA). The two groups were comparable as regards basal gastrins ($33\pm4{\cdot}3$ and $33\pm4{\cdot}9$ pg/ml respectively) and insulin-stimulated rise in gastrin ($32\pm7{\cdot}6$, $29\pm6{\cdot}2$ pg/ml) before operation.

After PGV mean basal gastrins doubled at 3 months ($67\pm22{\cdot}2$ pg/ml). Insulin-stimulated release fell at 10 days but was back to preoperative values at 3 months. After TVA basal gastrins were unchanged at 10 days and 3 months. Stimulated gastrin release fell to half the preoperative value ($16\pm3{\cdot}8$ pg/ml at 10 days, $14{\cdot}6\pm5{\cdot}2$ pg/ml at 3 months).

Rise in basal gastrin after PGV has been related to fall in acid secretion. However, in our preoperative subjects basal acid output was positively correlated with basal gastrin ($P<0{\cdot}001$), although insulin-stimulated gastrin release was negatively correlated with peak acid output to pentagastrin ($P<0{\cdot}01$).

Our findings differ from those of others, who found either unchanged basal gastrin after PGV (Clark et al., 1973) or a fall in basal gastrin after antrectomy (McGuigan and Trudeau, 1972).

47. Diurnal rhythm of gastrin and glucagon

B. W. ELLIS, R. C. G. RUSSELL, S. R. BLOOM and H. A. F. DUDLEY, *Surgical Unit, St Mary's Hospital, London*

A number of hormones involved in intermediary metabolism (e.g. growth hormone) have been shown to have a diurnal rhythm and specific secretion during various sleep stages (Pawel et al., 1972). However, there are no detailed studies of these aspects of the gastro-intestinal hormones; we have studied glucagon and gastrin in 6 healthy volunteers to determine whether there is either a diurnal rhythm or relationship to sleep stage.

Five volunteers had blood samples taken at 20-minute intervals over 24 hours and 1 volunteer had samples taken at 5-minute intervals overnight. All the subjects ate standard meals. Sleep was determined from electro-encephalogram, electro-oculogram and skin resistance recordings.

Glucagon levels showed marked fluctuation both on 20- and 5-minute sampling. Thus, the oscillation frequency of this hormone is likely to be less than 5 minutes. The levels were increased by food. The mean basal gastrin was 15 pg/ml. The rate of change of gastrin levels was slower than that of glucagon, and the oscillation frequency is probably at least 20 minutes. There was no apparent diurnal variation or association with sleep stage of either of these hormones.

It is concluded that the stages of sleep play no part in the control of these hormones and that studies of them can be undertaken without sleep recording. Meaningful data of glucagon levels would involve sampling at least every 2 minutes, whereas gastrin need not be sampled more often than every 20 minutes.

48. Effect of growth hormone release inhibitory hormone on gastric secretion in the cat

J. D. REED, MARGITTA ALBINUS, A. GOMEZ-PAN, R. HALL, M. H. THOMPSON, C. W. VENABLES, G. M. BESSER and A. V. SHALLY, *Departments of Physiology, Medicine and Surgery, University of Newcastle upon Tyne, St Bartholomew's Hospital, London, and VA Administration Hospital and Tulane University School of Medicine, New Orleans, Louisiana*

Growth hormone release inhibitory hormone (GH-RIH) has been shown to have a direct inhibitory effect on the gastric acid and pepsin secretory response to pentagastrin, and on the acid secretory response to food (Gomez-Pan et al., 1975). We have further investigated the effect of GH-RIH on intact and vagotomized gastric fistula cats.

An infusion of 10 μg/kg h^{-1} of GH-RIH inhibited by about 90 per cent, gastric acid secretion stimulated by 6·0 μg/kg pentagastrin subcutaneously, and 8 μg/kg h^{-1} given by intravenous infusion similarly inhibited the response to insulin 0·2 μ/kg intravenously. In contrast, the same GH-RIH infusion failed to inhibit the secretory response to 100 μg/kg h^{-1} of histamine (as base).

The results show that GH-RIH inhibits the response to all the stimuli we have studied except histamine, again raising the possibility that histamine is the final common mediator in gastric acid secretion.

GOMEZ-PAN A., REED J. D., ALBINUS M., SHAW B., HALL R., BESSER G. M., COY D. H., KASTIN A. J. and SCHALLY A. V. (1975) Direct inhibition of gastric acid and pepsin secretion by growth-hormone release-inhibiting hormone (Somatostatin) in cats. *Lancet* 1, 888–890.

49. Intraluminal oxygen in acute ischaemia of the small intestine

K. SHUTE (A. MARSTON), *Department of Surgery, Royal Postgraduate Medical School, London*

The mortality in acute ischaemia of the small intestine in man is over 90 per cent regardless of treatment. This experiment demonstrates the use of intraluminal oxygen in this condition in the rat.

Two comparable groups of 18 rats were anaesthetized with methoxyfluothane in oxygen. The superior mesenteric artery was clamped for 2 hours, then released, with immediate restoration of mesenteric circulation in all the animals. No treatment was given to the control group. In the treated group after 30 minutes' arterial occlusion 20 ml of gaseous oxygen were injected transmurally into the lumen of the small intestine. After release of the clamp, the mortality in each group was compared after 48 hours. Autopsies were carried out at death or after sacrifice at 48 hours.

Two rats in the control group (11 per cent) and 11 of those treated (61 per cent) survived for 48 hours. Statistical analysis showed this difference to be significant at the 1 per cent level ($P<0{\cdot}01$). All the animals dying before 48 hours had necrotic bowel filled with blood, whilst the survivors, sacrificed at 48 hours after occlusion, had viable bowel with macroscopically normal circulation.

Thus, intraluminal oxygen produced a statistically significant increase in survival in rats subjected to acute small intestinal ischaemia.

50. Effect of the histamine H_2 receptor antagonist, cimetidine, on insulin-induced gastric secretion in man

D. C. CARTER, R. LOGAN, J. A. H. FORREST, I. ANSELL, R. C. HEADING and D. J. C. SHEARMAN, *Department of Clinical Surgery and Gastrointestinal Section, Department of Therapeutics, Edinburgh University*

The histamine H_2 receptor antagonist metiamide is a potent inhibitor of gastric secretion in man (Carter et al., 1974; Milton-Thompson et al., 1974) but limited by bone marrow toxicity. Cimetidine is a new antagonist which does not appear to have toxicity problems.

Paired tests were carried out in 6 healthy volunteers. Insulin was infused for 150 minutes in a dose of 0·03 u./kg h^{-1}, and between 60 and 135 minutes 100 mg/h of cimetidine were infused. Saline replaced cimetidine in control studies. Volume, acid concentration and acid output were lower during cimetidine infusion, the acid output during the last 60 minutes of cimetidine being 4·36 ± 3·87 mmol/h compared with 17·73 ± 7·58 mmol/h in control tests (mean ± s.d. of mean; $P < 0{\cdot}001$). Pepsin output was not significantly affected by cimetidine. Plasma gastrin rose to a mean value of 57·8 ± 21·0 (s.e.m.) pg/ml after 150 minutes of cimetidine, compared with 40·4 ± 9·3 pg/ml in control tests ($P < 0{\cdot}15$).

Cimetidine is therefore a potent inhibitor of insulin-induced acid secretion in man, but this effect does not extend to pepsin secretion. If this compound remains free from toxicity it may have potential in the treatment of the peptic ulcer diathesis.

51. Value of perioperative acid tests in predicting recurrent ulceration after vagotomy

J. M. HOOD, E. F. ANNE SPENCER, K. D. MACRAE and T. KENNEDY, *Royal Victoria Hospital, Belfast*

In predicting recurrent ulcer after vagotomy, Kronborg (1974) found early postoperative insulin tests valueless, but preoperative acid output after pentagastrin correlated well with recurrence rates.

We have re-examined the value of preoperative pentagastrin test meals and postoperative insulin tests. In this series 274 prospectively studied patients have been followed up for 2–9 years after vagotomy of various types and 16 recurrent ulcers have been found, i.e. 5·8 per cent recurrence.

Preoperatively the mean basal acid in patients without recurrence was 4·2 mEq/h compared with 8·7 mEq/h in those with recurrence ($P < 0{\cdot}001$). With basal acid under 2 mEq/h the recurrence rate was 1·4 per cent compared with 18·5 per cent in those with more than 10 mEq/h. After pentagastrin stimulation there was no correlation between recurrence and either the peak or maximum output. Insulin tests showed a mean basal acid of 1·8 mEq in the patients with recurrence and 0·8 mEq in the remainder ($P < 0{\cdot}05$). Peak, maximum and total output were all significantly higher in those with recurrence ($P < 0{\cdot}001$). Strict Hollander criteria were positive in 24 patients, but only 5 of these developed recurrence.

These findings indicate that preoperative basal acid measurements and early postoperative basal and post-insulin levels all have predictive value.

52. Angiotensin II and vasopressin in haemorrhagic shock

M. A. TEHRANI, B. STUART, A. REYES, G. MCGARRITY, I. MCA. LEDINGHAM and J. J. MORTON, *University Department of Surgery, and MRC Blood Pressure Unit, Western Infirmary, Glasgow*

The renin-angiotensin system may be involved in the pathogenesis of irreversible haemorrhagic shock (Jakschik et al., 1974). The elevation of angiotensin II (AII) associated with shock may be prevented by a converting enzyme inhibitor (SQ20881) with the effect of increasing long term survival in dogs (Errington and Rocha E Silva, 1974). In the present experiments the effect of SQ20881 on cardiovascular, and in particular myocardial, performance was examined in two groups of spontaneously breathing, anaesthetized dogs subjected to haemorrhagic shock. Mean arterial blood pressure was reduced to 35–40 mm Hg and maintained for either 1·5 or 2 hours before retransfusion. In one of the two groups SQ20881 was given before and at an early stage of the shock. A third group of unbled dogs was also studied. Plasma AII, vasopressin and, when appropriate, AI were measured by a radio-immunoassay method.

In the group of 10 dogs not given SQ20881 plasma AII rose by 37 times during shock. During retransfusion 5 animals died of acute cardiac failure, and of the 5 survivors, only 2 had relatively normal left ventricular function.

In the group of 5 dogs given SQ20881 the plasma AII only doubled. All survived with relatively normal left ventricular function.

Plasma vasopressin was grossly elevated in both groups.

53. Energy levels in splanchnic organs following severe haemorrhage and reinfusion

T. V. KEAVENY, S. K. CUNNINGHAM and P. FITZGERALD, *Department of Surgery, University College, Dublin*

The concentrations of ATP, ADP and AMP were determined in splanchnic organs in anaesthetized dogs subjected to severe haemorrhagic shock and reinfusion (Crowell et al., 1969). Three groups of 7 animals each were studied: untreated bled animals, bled animals pretreated with allopurinol 50 mg/kg and unbled controls. The concentrations of ATP 2 hours following reinfusion are reported below. The total ATP + ADP + AMP showed the same pattern.

Plasma levels of the lysosomal enzymes acid phosphatase and β-glucuronidase were determined as indicators of lysosomal damage, since released proteases from splanchnic lysosomes have been strongly implicated in the irreversibility of shock. Plasma acid phosphatase and β-glucuronidase rose to very high levels in the untreated shocked group but were significantly lower in the allopurinol pretreated group ($P < 0{\cdot}0005$ and $P < 0{\cdot}01$ respectively).

This study indicates that: (1) in untreated severely bled dogs the ATP concentrations in pancreas, liver and duodenum are not restored to normal 2 hours following reinfusion; (2) allopurinol pretreatment results in essentially normal ATP, ADP and AMP concentrations in these organs; (3) allopurinol pretreatment reduces the rise in plasma lysosomal enzymes.

	(1) Unbled controls	(2) Bled untreated	(3) Bled allopurinol-pretreated	Significance of (2) vs. (3) (*P*)
Pancreatic ATP	1·921 ± 0·26	0·898 ± 0·30	1·780 ± 0·34	< 0·0005
Liver ATP	1·195 ± 0·29	0·620 ± 0·17	1·192 ± 0·47	< 0·01
Duodenal ATP	1·804 ± 0·09	1·218 ± 0·42	1·874 ± 0·36	< 0·025
Splenic ATP	0·721 ± 0·28	0·571 ± 0·17	0·606 ± 0·05	NS

All the results given as the ± s.d. in μmol/g wet weight. NS, Not significant.

54. Comparison of dextran 70 and hydroxyethyl starch in volume replacement

J. A. R. SMITH, J. N. NORMAN, A. SMITH and G. SMITH, *Department of Surgery, University of Aberdeen*

Both plasma and dextran solutions are commonly used for volume replacement in shock therapy but both have many disadvantages. Hydroxyethyl starch solution (HES) may have the advantages of dextran without its disadvantages, but its evaluation, particularly in shock, is incomplete. This study aims at comparing dextran 70 with HES in an established canine shock model.

Refractory shock was induced in 20 dogs by maintaining arterial pressure at 40 mm Hg by haemorrhage for 2 hours. At the end of this period the remaining shed blood was discarded and sufficient dextran or HES was infused to maintain central venous pressure at 2–4 mm Hg. Measurements of cardiac output, stroke volume, peripheral resistance and oxygen availability, consumption and debt were made at 15-minute intervals for 2 hours.

Both groups of dogs became progressively haemodiluted to a minimum haematocrit of 22 per cent of the resting value and both groups required similar volumes of fluid to maintain normovolaemia. Cardiac output, peripheral resistance and oxygen availability were similar in both groups, but tissue oxygen consumption was significantly greater in the groups given HES and the oxygen debt was repaid in this group. There was no evidence that haemodilution altered the course of shock and there was no significant difference in the dilution and expansion achieved by dextran 70 or HES. This suggests that HES is worthy of further consideration.

55. Effect of heparin and of acid-citrate-dextrose solution on screen filtration pressure of blood in experimental hypotension

B. J. PARDY and H. A. F. DUDLEY, *Surgical Unit, St Mary's Hospital Medical School, London*

Heparin is widely used to lessen the risk of microthrombosis in areas where perfusion is temporarily reduced and also appears to be effective when disseminated intravascular coagulation occurs as a consequence of generalized hypoperfusion. Nevertheless, in clinical practice isolated limbs do not always recover after restoration of their circulation, and experimentally heparin has not prevented microcirculatory obstruction in either the rat kidney (Diethelm and Wilson, 1971) or adrenal (Kovacs et al., 1966).

Screen filtration pressure (SFP) is a measure of microaggregation of blood; therefore, we have studied the effects of heparin and acid-citrate-dextrose (ACD) on SFP during and after haemorrhagic hypotension induced in 5 greyhounds by a bleed to a mean pressure of 90 mm Hg sustained for 3 hours and followed by reinfusion. SFP is expressed as the fourth root of the difference in pressure required to force saline at constant rate through a 20 μ filter before and after the passage of a standard amount of blood.

The results are tabulated and show that heparinized blood always causes more obstruction than does ACD blood; during and after shock the difference is greatly increased. Therefore, heparin may not be the ideal agent to protect the microcirculation during hypoperfusion.

	SFP			
	After induction	2 hours before shock	During shock	4 hours after shock
ACD blood	1·43±0·15	1·53±0·11	1·86±0·15	1·53±0·28
Heparinized blood	1·89±0·17	1·65±0·16	3·26±0·12	2·78±0·29

56. A new approach to thrombolytic therapy

V. V. KAKKAR and S. SAGAR, *Department of Surgery, King's College Hospital Medical School, London*

Several studies have now clearly shown that fibrinolytic therapy is highly effective in dissolving venous thrombi and pulmonary emboli. The most satisfactory method of streptokinase administration for producing maximum thrombolytic effect with the minimum hazard to the patient remains to be determined. In this paper we report the rationale and the preliminary results of a study where small doses of streptokinase were given intermittently in combination with plasminogen infusion to produce maximum thrombolytic effect.

In vitro studies were performed using 20 human thromboemboli removed at post-mortem. An initial perfusion with ^{131}I-labelled plasminogen showed an uptake by the thrombus about 3 times higher than that of the perfusion fluid. Subsequent perfusion with buffer containing streptokinase produced rapid and complete lysis. Twelve consecutive patients with extensive deep vein thrombosis confirmed by venography were divided into two groups: one group received 600 000 units of streptokinase every day for 5 days, and the other group 80–120 mg of plasminogen followed by 600 000 units of streptokinase, again for 5 days. No lysis of thrombi was observed in the group receiving streptokinase only, while 80 per cent of thrombi were completely lysed in those receiving streptokinase and plasminogen.

Our conclusions are that the new approach is safer, cheaper and much more effective than conventional thrombolytic therapy.

57. Coagulation and fibrinolytic responses during operative surgery

M. J. BUTLER, B. J. BRITTON, MURIEL SMITH, CHRISTINE HAWKEY and M. H. IRVING, *Departments of Surgery, St Bartholomew's Hospital, London, Hope Hospital, Salford, and the Nuffield Institute of Comparative Medicine, London Zoo*

Previous studies have demonstrated the changes in coagulation and fibrinolysis that follow operation but not the changes that occur during the operation itself. These changes have particular relevance as most postoperative venous thromboses are apparent within 48 hours and are thought to begin during operation.

Fourteen measurements of coagulation and fibrinolysis have been studied in 50 patients during elective abdominal surgery. Samples were taken immediately before operation, after induction of anaesthesia, halfway through the operation and at the end of operation.

Whole blood clotting time (WBCT), measured by thrombelastography, showed progressive shortening, this time at the end of the operation being significantly shorter than that of the preoperative sample ($P<0·001$).

No significant changes occurred in the activity of Factors II, V and X, but there was a highly significant rise in Factor VIII ($P<0·001$). This rise is unlikely to be of major significance in the shortening of WBCT as similar rises after exercise and venous occlusion are not accompanied by comparable WBCT changes.

Progressive activation of fibrinolysis began after the induction of anaesthesia, the changes being maximal by the midpoint of the operation ($P<0·005$), but tending to reverse by the end of the operation. Although there is no detectable difference between the coagulation and fibrinolytic responses of patients who develop deep vein thrombosis and those who do not, the marked hypercoagulability that develops during operation is likely to be a contributory factor in the development of venous thrombosis.

58. Nutritional skin blood flow before and after chemical sympathectomy

J. J. MORRICE, A. M. HARPER, D. W. SHORT, W. REID, J. K. WATT, J. POLLOCK and L. J. BLUMGART, *University Department of Surgery, Royal Infirmary, and Peripheral*

Vascular Unit, Royal Infirmary and Belvidere Hospital, Glasgow

The measurement of the clearance of ^{133}Xe from the skin is a reliable indication of capillary blood flow and therefore nutritional flow (Sejrsen, 1971).

We have used the epicutaneous ^{133}Xe technique (Sejrsen, 1968) to measure nutritional skin blood flow in the dorsum of the foot in normal controls and in patients with peripheral vascular disease before and after phenol injection of the lumbar sympathetic chain.

Under uniform resting conditions and at a constant room temperature (20 °C), ^{133}Xe clearance was measured with a scintillation detector, and the dermal nutritional flow calculated from the fast component of the resultant bi-exponential clearance curve. In 33 control patients (66 limbs) a mean value of $5{\cdot}2 \pm 1{\cdot}8$ (s.d.) ml/100 g tissue min^{-1} was obtained.

In a group of 33 patients with peripheral vascular disease skin blood flow before and after unilateral phenol block was measured. On the day following phenol injection a mean increase in skin flow of 71 per cent was obtained ($P < 0{\cdot}005$). At 1 month after injection the mean increase over the pre-injection flow was 51 per cent ($P < 0{\cdot}005$).

Simultaneous measurements of the skin flow in the non-sympathectomized limb showed no significant alteration in skin flow before and after injection at either 1 day or 1 month.

We conclude that phenol injection of the lumbar sympathetic chain effectively increases nutritional skin blood flow.

59. A blind clinical trial comparing ultrasound detection with established techniques to predict the site of incompetent perforating veins

K. G. BURNAND, T. F. O'DONNELL, M. LEA THOMAS and N. L. BROWSE, *St Thomas's Hospital, London*

Accuracy in excess of 80 per cent has been claimed (Miller et al., 1971) for ultrasound localization of incompetent perforating veins (ICPV) comparable to that previously reported for phlebography (Thomas et al., 1972). Unlike previous reports, this is a blind study which simultaneously compares three methods of ICPV detection with venous pressure profiles and operative findings.

ICPV localization on the medial side of 32 legs was made by clinical examination, ultrasound and ascending phlebography, each by a different observer. All the patients had pressure measurements made in a foot vein while standing at rest and during excercise. ICPVs were confirmed at operation (a long medial incision) by a positive bleed-back test.

The results of each test is expressed as a percentage of the surgical findings.

	Correct	False positive	False negative
Clinical	53	69	47
Phlebography	57	21	43
Ultrasound	67	113	33

The only significant difference in these results is that phlebography produces less false positives than ultrasound.

All the legs whose pressure drop on exercise was less than 40 per cent, in the presence of a thigh tourniquet, had ICPVs. If the foot vein pressure during exercise is abnormal we suggest that the only way to detect all the ICPVs is by using a full medial calf incision.

Obituary

Vincent Zachary Cope

KT, MD, MS, FRCS

1881–1974

ZACHARY COPE lived to the ripe old age of 93, but this was probably the least of his many varied achievements. Even in growing older, he never grew old, as was well evidenced by the publication of the fourteenth edition of the book for which he is most famous, *Early Diagnosis of the Acute Abdomen*, in 1972, less than 3 years before he died and 50 years after the first edition appeared in print. As an erstwhile dresser, registrar and colleague of his I am proud to possess a signed copy of this last edition—the signature clear and legible, the message above it lucid and warm.

Surely no surgical textbook has ever had the active life of this one. Generations of young surgeons all over the world have reason to be eternally grateful to him for its sound practical wisdom. In so many ways it reflects the character of its author, not only in its longevity but in its clarity of thought and expression, its basic common sense and its infallible appreciation of primary values.

Zachary Cope, the son of a north country Methodist minister, was a modest man with the quiet courtesy and manner of the Victorian era. But this apparently unhurried approach to life, of which he enjoyed to the full so many facets, hid a dynamic and intense personality which enabled him to cover, seemingly quite unruffled, a vast and varied field of interests in which he was all too often unseen and unheard and certainly to far too great an extent unsung.

In his youth qualification from St Mary's with honours in Surgery and Forensic Medicine in the London MBBS of 1905 was followed by the MD in 1907 and the MS and FRCS in 1909, and culminated in appointment to the St Mary's consultant staff in 1911. Man and boy he was an ardent protagonist of St Mary's and the hospital owes him much both in example and precept. In the First World War he served typically as a humble and hard-working RAMC captain in several theatres of war, was mentioned in dispatches and from the experience he gained in Mesopotamia produced his first venture into the world of medical literature—*Surgical Aspects of Dysentery*, published in 1921. Then in the period between the two World Wars came his time of fulfilment as a sound safe surgeon, as a gifted clinical diagnostician, as a highly successful and popular teacher and as an invaluable guide, counsellor and friend to a vast number of students, younger staff, colleagues and all sorts of medical institutions, associations and colleges. He was essentially a very human person—outgoing and warm-hearted. Though himself abstemious, the natural warmth of his personality embraced all those with whom he came into contact. He seemed to have an inexhaustible store of goodwill towards men—and it is very doubtful if he ever had a real enemy.

His students showed by deed their appreciation of his teaching as they flocked to his informatively instructive ward rounds; his patients trusted him implicitly—none more so than the children who came under his care, surely the indelible hallmark of a good doctor; and his juniors reacted automatically to his genuine, positive and continuing interest in them and their future. Who amongst those fortunate enough to have received them can have failed to be delighted by the amusing little outpourings of doggerel verse that arrived punctiliously every Christmas, or at times of recognized success.

To those who really knew him he showed a rather unexpected sense of quietly sardonic humour.

In this College his active service stretched over many valuable years; a full term Councillor and a Vice-President, a member of the Court of Examiners and a prolific giver of eponymous lectures. Few men can have equalled his record of four Hunterian, the Arris and Gale, the Vicary, the Tomes and the Bradshaw lectures!

His chief institutional interests outside the College lay principally with the BMA, on the Council of which he served for many years, ultimately becoming Vice-President and for which he chaired many committees, perhaps the most important being that on medical auxiliaries; and with the Medical Society of London of which he became President, Orator and the giver of its annual Lettsomian lecture. But he was also deeply involved in the affairs of the Royal Society of Medicine of which for many years he was Honorary Librarian and was very deservedly made an Honorary Fellow. He received a similar recognition from the Faculty of History of the Worshipful Society of Apothecaries, and in due course, most fittingly (and to the great delight of his host of friends), received the accolade of Knight Bachelor in the first Honours List of the Queen in the Coronation Year.

In the Second World War he held the post of Sector Medical Officer in the Emergency Medical Service and did yeoman work 'standing in' for many of his junior colleagues. Not surprisingly, this led to the very responsible task of chairing the National Medical Manpower Committee in the immediate post-war years.

At this stage he began to turn more to his second great love—that of literature. Zachary Cope was an erudite man, well and widely read, and undoubtedly had a natural flair for writing. At no time, however, did he lose his abiding interest in surgery and medicine and, though himself remaining essentially the humane and clinical exponent of the art, he had a lively appreciation of the dramatic and dynamic changes that science and technology were effecting in modern surgery. His writings were protean and prolific, and the results highly informative and easily readable. As examples, apart from his surgical books and articles, he wrote the *History of the Royal College of Surgeons of England* in 1959 and the *History of St Mary's Hospital Medical School* in its centenary year; he edited two volumes (clinical) of the *Medical History of the* 1939/45 *War*, and several biographies including those of Florence Nightingale, Cheselden and Aimroth Wright. All this, as one can see, amounted to a stupendous amount of work, but it was work that really gave him keen personal pleasure—he called it his 'self-indulgence'—and amazingly enough it still left him a modicum of time to develop his minor interests of music and, perhaps rather surprisingly, motoring, of which he was an early pioneer.

In his kaleidoscopic life Zachary Cope ensured for himself an enduring place in the history of surgery. His friends—and they were legion—will mourn his passing, but they will know their own lives are the richer for his having lived. His mind and his spirit remained unquenchable to the end—a man of many parts—a man small in stature but big in heart.

Br. J. Surg. Vol. 62 (1975) 670–672

Reviews and notices of books

A Textbook of Surgery

Edited by Mahadevan, Madras. 250×185 mm. Pp. 1167+xiv. Illustrated. 1974. Bombay: Asia Publishing House. 125R.

WITH the changing face of surgery the writing of a general textbook that is completely acceptable to all surgeons has become an impossibility. Mr Mahadevan is to be congratulated on his achievement in compiling this book, which is aimed primarily at meeting the needs of medical students. He has been handicapped by the availability of suitable paper which has necessitated using one type of paper for the text and another for the illustrations. This has led to the grouping of illustrations separately from the text. The illustrations make full use of the vast amount of clinical material available, but unfortunately in places the reproduction is not clear. The long list of plates at the beginning of the book is rather laborious.

In a book as comprehensive as this it is not surprising that one may disagree with some of the opinions expressed, but there are certain points which call for comment. In the classification of leprosy the distinction between lepromatous, dimorphous and tuberculoid types could be made clearer. When possible, in the prophylaxis of tetanus it would be safer not to use ATS, but to give toxoid covered by a week's course of penicillin which could be given orally. In the management of fluid and electrolyte balance the term 'dextrose/saline' is used a little loosely, and while M/6 lactate is mentioned in the management of acidosis, sodium bicarbonate solution is omitted. Under anaesthesiology, no mention of extradural anaesthesia other than caudal block is made, and there is no mention of the management of diabetes which is so common in South India. External cardiac massage and early intravenous sodium bicarbonate are omitted in the management of cardiac arrest. Compression sclerotherapy for varicose veins is difficult to practise in India, but it should be mentioned under the heading of injection therapy.

An alarming piece of advice is the combination of hyalase with adrenaline for subcutaneous infiltration in thyroidectomy, and no mention is made of the use of propranolol in thyroid crisis. Under hyperparathyroidism it would be correct to say that if hyperplasia is found it involves all the glands. In the management of Stage 1 or 2 carcinoma of the breast no reference is made to simple mastectomy, and under radical mastectomy there is no mention of the Patey type of procedure. The section on hiatus hernia would be more balanced if some space could have been given to surgical procedures. When describing the Ramstedt operation for pyloric stenosis one would not disagree that often in India it is safer to operate under local anaesthesia, but one could well disagree with the statement that 'open ether is safest'. The statement that gastric ulcers are commoner than duodenal ulcer in Africa is not correct. Vagotomy in the management of duodenal ulcer—a big problem in South India—is but briefly presented. Fractional test meals are mentioned, although these have been largely replaced by estimations of maximal acid output when required, but there is no reference to augmented histamine or pentagastrin test meals. Gastroscopy with the rigid instrument is referred to but no mention is made of modern endoscopy.

The description of the management of rectal prolapse is incomplete without reference to the Charles Wells operation or Thiersch's procedure. Excision is advised as the surgical procedure for chronic fissure in ano. One would not agree with the statement that when the serum amylase is raised above 150 Somogyi units acute pancreatitis should be suspected, or with the advocacy of biopsy in chronic pancreatitis. Not all would agree that every case of chronic retention of urine requires slow decompression—it is probably more important that such cases should be adequately hydrated. Such cases could also have a period of preparation by urethral catheter drainage and not all require a two-stage prostatectomy as stated. There is no description of the technique of passing an urethral catheter. Retropubic prostatectomy is not described. Most of us would not excise a congenital hydrocele in small children. Phenoxybenzamine and β-blockers should be given a place in the surgery of phaeochromocytoma.

Despite all these criticisms this book is a monumental achievement, but one wonders whether it would not have been better to have concentrated on the surgical problems which are peculiar to India. Much of the surgery practised in India differs little from that practised in this country. If available locally, it would be hard to improve on some of the well-tried and reasonably priced English textbooks. Such books would provide all the necessary background, and the efforts of experienced Indian surgeons could be directed to producing supplementary textbooks dealing with problems such as abdominal tuberculosis, hydatid disease, splenomegaly, volvulus and leprosy which are commonly found in India.

F. I. TOVEY

Children's Fractures

Mercer Rang, Toronto, and 5 contributors. 278×215 mm. Pp. 238+xiv. Illustrated. 1975. Oxford: Blackwell Scientific Publications. £15·40.

THIS book on children's fractures begins with a parable in the Preface which the reviewer had great difficulty in understanding. In the Acknowledgements the author observed that he had been persuaded that it was a small step to transform material from an instructional course into a book. This must account for the unusual, and often exasperating, use of mixed types of illustrations, of ancient photographs (of Monteggia and Galeazzi) and of cartoons. Indeed the one illustrating Waddell's triad is repeated twice. I do not believe that Andy Capp's form of modern pop art drawings with almost Zip! Zam! Zoom! captions makes a textbook any more interesting or the observations any more definitive, especially at a price of £15·40.

The use of technetium radioactive scanning for diagnosing stress fractures does not appear to be a major breakthrough as suggested in the caption of Fig. 0.1. In growing individuals there are too many uncertainties, and indeed hazards, to balance any refinement in their diagnoses.

This book is certainly not for medical students and residents as it does not contain sufficient detail or statistics to support many of the observations. This is a great pity because it is very obvious that Dr Mercer Rang has had a unique experience over the past 10 years in The Hospital for Sick Children, Toronto. Its immense patient population should provide a challenging opportunity for statistical analysis and follow-up. On reading through the text one had the feeling of stumbling over the chapters on chest, gastro-intestinal and genito-urinary tracts and craniocerebral injuries. The style of writing suddenly changes, becomes quite simple and less than that required for a surgical resident. Even the heading 'Bibliography' becomes 'Recommended reading'.

The bibliography throughout is extensive and modern but even so several authors are mentioned in the text without being given a reference, e.g. Weicz et al. (1973).

The author writes about his relationship with both the injured child and the parents and about his own concern for iatrogenic lesions. Learning of these fundamental reactions best comes during the resident's apprenticeship to his mentor. It is difficult to read and appreciate these very personal reactions without having experienced them or seen how they are handled by the teacher.

This is a very 'personal' book from an obvious expert and surely will have its greatest appeal to those who know Dr Mercer Rang and who have been taught by him.

R. B. DUTHIE

Postgraduate Surgery Lectures 2

Edited John McFarland, Liverpool. 215 × 140 mm. Pp. 122 + ix. Illustrated. 1974. London: The Butterworth Group. £2·65.

This is the second volume in the *Postgraduate Surgery Lectures* series selected from the 1972/73 season at the Liverpool Medical Institution. Eight of the lecturers have presented for publication subjects in which they are expert.

The book opens with a lively chapter on postoperative peritoneal adhesions which represents a useful summary of the subject and practical suggestions. This is followed by the problem of haemophilia in abdominal surgery, the sequelae of head injuries and the problems of testicular tumours. The next chapters deal with obstructive uropathy, cholecystectomy, the controversial subject of the treatment of gastric ulcers and lastly metabolic care in surgery.

This is a readable and enjoyable book, useful for FRCS candidates and all who are interested in general surgery.

IAN MCCOLL

A Guide to Disaster Management based on Proceedings of an Inter-service Conference held in the Walton Conference Centre, The Southern General Hospital, Glasgow, in September 1973, and a Report on Disaster Response in America and Canada following the Tornadoes of April 1974.

Edited W. Sillar, Glasgow. 298 × 210 mm. Pp. 115. 1974. Glasgow: Action for Disaster. £2.

With the publication of this book, another valuable contribution has been made to disaster technology. In 1973 Action for Disaster, a Scottish voluntary organization concerned with the saving of human life, arranged a meeting in Glasgow of representatives of all emergency services to discuss disaster management. Both the police and fire service spokesmen emphasized the importance of defining roles and areas of responsibility and the need for liaison, communication and agreement over command in disaster management, but the representative of the ambulance service drew attention to the fact that the role of his service in casualty care, as well as transportation, was often not fully appreciated by the other emergency services.

Two papers of particular interest to clinicians will be those from Swedish contributors: 'The Role of the Medical Services' and 'The Doctor at the Disaster Site'. The book also includes a report on a visit made by the Editor and a colleague to North America to study the disaster response following a number of tornadoes. Many of the lessons learned the hard way by others have yet to be applied to disaster planning in the United Kingdom.

P. E. A. SAVAGE

Tumors of the Major Salivary Glands (Atlas of Tumor Pathology, Second Series)

A. C. Thackray and R. B. Lucas, London. 260 × 200 mm. Pp. 144 + xii, with 163 illustrations. 1974. Washington, DC: Armed Forces Institute of Pathology. $8.85.

The publication of this book has been an important event in surgical pathology. One fascicle of the second series of the *Atlas of Tumor Pathology* that is being published by the United States Armed Forces Institute of Pathology under the general editorship of Dr H. I. Firminger, it describes the various lesions that may present as a lump in a salivary gland in terms of the World Health Organization scheme for the 'Histological Typing of Salivary Gland Tumours'. Professor Thackray was, of course, one of the authors of that scheme, and the publication of this book so soon after the scheme itself should do much to consolidate the position of this classification as the premier choice of pathologists all over the world.

After an introduction concerned with embryology, anatomy and physiology, the various tumours are described under the general headings of definition, clinical features, histogenesis, gross and microscopic appearances, treatment and prognosis and differential diagnosis. The illustrations are marvellously clear, whether one looks at the 155 black and white figures or the 8 illustrations in colour.

The whole book is imbued with the personality of the authors, who describe pathology not as an end in itself but as a way to a better understanding of how a patient should be treated. There are wise remarks on the pitfalls of trying to make a histological diagnosis from small fragments of a tumour (such as may be produced by drill biopsy), on the dangers of attempting to cure a pleomorphic adenoma by enucleation and on the value of radiotherapy as an adjunct to excision in the more malignant lesions.

All in all, no one who is particularly interested in the management of patients with salivary gland tumours can afford to do without this book; it is cheap at the price.

MICHAEL HOBSLEY

Sémiologie Chirurgicale

Lucien Léger, Paris. 270 × 215 mm. Pp. 480 + xiii, with 989 illustrations. 1974. Paris: Masson et Cie. 100F.

This is an interesting book and primer to surgical studies, relating the presentation of the patient and the clinical signs, all illustrated with appropriate line drawings and radiographs of good quality interspersed with apposite statements tinged with Gallic wit.

It covers the whole field of surgery including gynaecology but excluding ophthalmology and otorhinolaryngology. It can be strongly recommended to preclinical students as, by means of short sentences with descriptive drawings, it teaches basic orthodox surgery and pathology.

Unfortunately, it would probably not bear translation because of the excellence of similar books in the English language, but it satisfies a very real need in France and French-speaking countries. The preface is notable for the comment on continuing changes in the syllabus and lack of facilities for students to see clinical material—a comment apposite for this country as well.

JEAN CLAUDE GAZET

Trauma Management

Edwin F. Cave, John F. Burke and Robert J. Boyd, Massachusetts. 253 × 180 mm. Pp. 1237 + xviii. Illustrated. 1975. London: Lloyd-Luke. £42·75.

I do not know what to say about this book. Partly this is because its original inspiration and continued bias are orthopaedic and I am not skilled in that field; partly because I recoil from the expensive production on hyperglossy paper; partly because I find it difficult to conceive of who would buy a book in a changing subject which costs what this one does; partly because in spite of the monumental price my review copy was delivered with a number of flawed pages. Never was so little offered in so much bulk at such a price.

These things said and spleen vented, what has this book to offer? There are reasonably up-to-date, well-written accounts of the metabolic response to injury, largely the responsibility of Dr Burke; exhaustive treatment of fracture problems, with, as might be expected in a centre like the Massachusetts General, a considerable emphasis on the patient who has gone wrong elsewhere. The approach to areas where I have greater familiarity seems less complete, which makes one doubt the overall authority of the work. Seat belt visceral injuries and chance vertebral fractures I could not find. Selective approach to civilian penetrating abdominal injury is dismissed. Stress ulceration merits only a paragraph and treatment is not considered. Acute acalculus cholecystitis is not mentioned in spite of the Vietnam experience. All in all the vaulting ambition of this book has o'er leaped itself.

Even if we do not insist on the comprehensive text—to which we might feel entitled in view of the weight and price—it is possible to cavil at the failure to give definite advice on what to do or how to reach a decision. All too often every possibility is listed without a firm recommendation being made, as if the writer was anxious to display erudition without exercising responsibility.

The volume may go down in history as a monument to the industry of its contributors but it will little advance the scholarship of surgery.

H. A. F. DUDLEY

Soviet Research in Pharmacology and Toxicology
William H. Fitzpatrick. 230 × 150 mm. Pp. 322+xii. 1974. Maryland: US Department of Health, Education and Welfare. $3.05.

THIS book is a publication of the John E. Fogarty International Center for Advanced Study in the Health Sciences. It was published in 1974 and is supported by the US Department of Health, Education and Welfare, Public Health Service, National Institutes of Health. Its aim is to examine the subject so that others may have a better perspective of work in the field in the USSR. A secondary objective is to encourage co-operation between health scientists and administrators of various countries.

The book covers a wide range of subjects in pharmacology and toxicology. Those involved in research will be well aware of much of the Soviet work because these articles are cited in many abstracting journals, often with a brief English summary. It seems unlikely that the contents will be of particular interest to surgeons, as might be expected from the title. Its main use would be to give a broad view of the kind of work going on rather than to give information in depth on any particular line of research.

J. G. MURRAY

Alexis Carrel. Visionary Surgeon
W. Sterling Edwards and Peter D. Edwards, Albuquerque, New Mexico. 230 × 150 mm. Pp. 143+x, with 15 illustrations: 1974. Springfield, Ill.: Charles C. Thomas. $5.

THE life of Alexis Carrel was full of interest, for he was not only a great scientist and practical surgeon but also a mystic. Carrel has been called the father of vascular surgery because of his techniques of arterial suture and blood vessel grafts.

There are still many surgeons who remember Carrel's irrigation apparatus, which was extensively used in the First World War in the treatment of septic wounds and gas gangrene.

Charles Lindleigh, who was a co-worker of Carrel in many of his investigations, writes a laudatory foreword to this biography.

Professor Sterling Edwards and his son Peter have put the medical profession in their debt by writing this excellent biography. It must not be forgotten that Carrel's Nobel Prize in Surgery was a token of his international regard, for he had a most original and stimulating mind. Although he was the first to produce an artificial heart, he was also responsible for techniques of tissue culture. A very versatile and exceptional surgeon.

CECIL WAKELEY

Book notices

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and those having the greatest interest to our readers.]

Regulation of Gene Expression in Eukaryotic Cells
Edited Maureen Harris and Brad Thompson. 230 × 150 mm. Pp. 127+vi. Illustrated. 1974. Maryland: US Department of Health, Education and Welfare. $4.15.

National and Regional Health Planning in Sweden
Vicente Navarro, Baltimore. 230 × 145 mm. Pp. 244+xvii, with 35 illustrations. 1974. Maryland: US Department of Health, Education and Welfare. $2.55, paper covers.

Fonctions et Bilans Articulaires
Ch. Rocher and A. Rigaud, Bordeaux. Third edition. 160 × 240 mm. Pp. 320, with 215 illustrations. 1974. Paris: Masson et Cie. 76F.

Soviet Biomedical Institution: A Directory
A publication of the Geographic Health Studies Program of the John E. Fogarty International Center for Advanced Study in the Health Sciences prepared under an Interagency agreement with the Library of Congress. 268 × 105 mm. Pp. 553+xviii. 1974. Maryland: US Department of Health, Education and Welfare. $5.95.

Diseases of the Esophagus. Volume 3
G. Vantrappen, J. Hellemans and contributors. 248 × 168 mm. Pp. 877, with 358 partly coloured illustrations. 1974. Berlin: Springer-Verlag. DM.390.

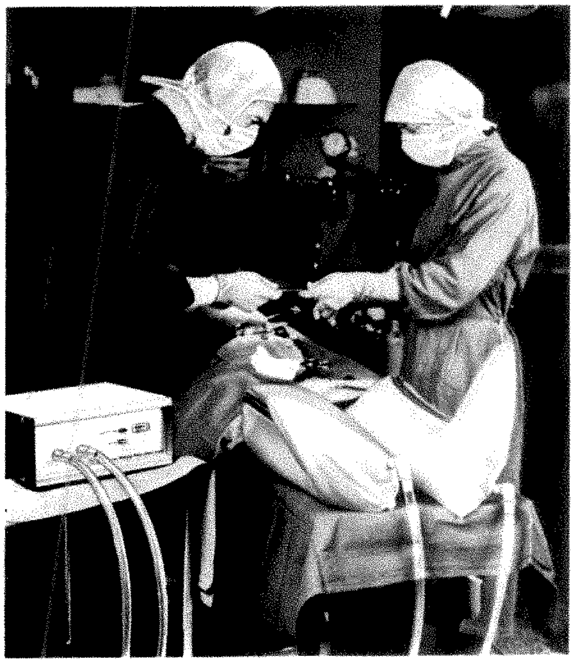
New Parts for Old, the Age of Organ Transplants
John G. Deaton, Austin, Texas. Pp. 160. Illustrated. 1974. Palisade, New Jersey: Franklin Publishing Co. Inc. $7.40.

Metabolic Disorders of Bone
C. R. Paterson, Dundee. 232 × 155 mm. Pp. 373+x. Illustrated. 1975. Oxford: Blackwell Scientific Publications. £8·25.

The ABC of Acid–Base Chemistry
Horace W. Davenport, Chicago. Sixth edition. 150 × 225 mm. Pp. 124+vii. Illustrated. 1974. London: University of Chicago Press. Cloth £4·25; Paper £1·75.

Smooth Muscle Regeneration. (Monographs in Development Biology)
John K. McGeachie, Nedlands, Western Australia. (Series editor A. Wolsky.) 225 × 155 mm. Pp. 90+vii, with 39 illustrations. 1974. Basel: Karger. No price given.

BOC Roberts Venous Flow Stimulator tackles the problem of d.v.t. where it starts



Every patient undergoing surgery is at risk from deep vein thrombosis. According to the Registrar General's reports, the incidence of death from d.v.t. - induced post-operative pulmonary embolism, is steeply rising.

It has been demonstrated* that the occurrence of deep vein thrombosis can be dramatically reduced by the application of intermittent calf compression per-operatively to prevent venous stasis. This procedure is, however, successful only when the pressure cycle conforms to blood flow dynamics. Critical considerations are:

- ● The duration and magnitude of the applied pressure.
- ● The timing of the pressure cycle to give vessels the optimum time to refill between compression phases.

Only the BOC Roberts Venous Flow Stimulator meets these criteria precisely and automatically. Clinical trials indicate that the apparatus can eliminate over 75% of cases of post-operative d.v.t. without the need for chemical intervention.

If you would like to know more about this equipment, please write or telephone us at the address below.

*Roberts, V.C. and Cotton, L.T. (1974a) British Medical Journal 1 358

Belfast table

A table for perineal and general surgery which is designed to allow the patient to be placed in lithotomy position without being lifted or pulled down the table.

Chas. F. Thackray Limited, Head Office: P.O. Box 171 Park Street, Leeds LS1 1RQ.

What's so different about a routine foley catheter?

At a glance the new Simplastic foley catheter is different – it's the clear PVC one. For your patients the difference is simply that they're more comfortable.

- The extra-large lumen size of SIMPLASTIC foley catheters allows smaller gauges to be selected, thereby reducing urethral trauma and the risk of infection. Just compare a 22Ch latex catheter with a 16Ch Simplastic foley catheter – the internal lumen sizes are almost identical.

- Easy to insert, SIMPLASTIC foley catheters are soft and supple at body temperature providing maximum patient comfort.
- Made from implant tested PVC, SIMPLASTIC foley catheters are less likely to cause urethral irritation.

The new
SIMPLASTIC
routine-use foley catheters
Simply better for your patient

INJURY

The British Journal of Accident Surgery

Editor, R. L. BATTEN, FRCS(Eng)

Injury provides a focal point of information for those engaged in the many fields of medicine which accident surgery involves. Contributions from all over the world provide well-organized and comprehensive coverage of every aspect of care of the injured. Original articles take up a large section of INJURY and, as accident surgery is so often concerned with the individual patient, reports of interesting and complex cases are included. To keep the reader informed of the latest progress, INJURY contains details of current research and of new drugs and medical instruments. Reviews of new books appear regularly and, of particular value in a field of medicine which often has a debt to other specializations, INJURY devotes some of its space to abstracts from a wide range of publications on related subjects.

BURNS including Thermal Injury

The Journal of the International Society for Burn Injuries

Editor, J. E. LAING, FRCS

To counter the high mortality and morbidity caused by burn injuries needs the teamwork of a wide range of specialists: treatment of the patient can involve plastic, paediatric and orthopaedic surgeons, biologists, immunologists and bacteriologists, while the rehabilitation of the patient can need the efforts of occupational therapists, physiotherapists, psychiatrists and social workers. This new journal is published to foster the exchange of information amongst all those engaged in preventing and minimizing the effects of burn injuries. BURNS is sponsored by the International Society for Burn Injuries, whose aims are to transcend national boundaries in improving the prevention and care of burns by education, research, practical advice and assistance, and the encouragement of cooperation between all countries and all specialists.

ARMOUR TEMPORARY BIOLOGICAL DRESSING CAN SOLVE THE IMMEDIATE PROBLEM OF TISSUE LOSS COVERAGE AND REPAIR

effective in the treatment of

- partial thickness burns
- debrided full thickness burns
- traumatic skin loss injuries
- soft tissue defects
- decubitus and vascular ulcers

The many advantages of using a biological dressing are

- dramatic reduction of pain
- reduction of fluid and protein loss
- reduction of heat and energy loss
- reduction of infection
- increase in mobility
- protection of exposed tendons, vessels and nerves
- promotion of healing
- psychological improvement of the patient
- improvement of scarring
- In full thickness burns, used as a "test material" to predict the readiness of the granulating bed to accept autograft. This results in a more economical use of autograft material.

Armour porcine skin dressings are presented in sterile lyophilised form, can be conveniently stored without refrigeration and may be reconstituted prior to use in sterile water or balanced electrolyte solution.

Package and size availability is as follows:
Boxes of 5 x 1 sq. ft. roll 3″x 48″
Boxes of 5 x ¼ sq. ft. roll 3″x 12″
Boxes of 10 Patches 2½″x 4″
Boxes of 5 x Wide Strip 8″x 18″
Boxes of 5 x Wide Half Strip 8″x 10″

New and Revised 11th Edition

AUGUST

Synopsis of Surgical Anatomy

Edited by D. J. du PLESSIS
CHM (Rand), FRCS (Eng)

Head of the Department of Surgery, University of Witwatersrand, Johannesburg; Chief Surgeon, Johannesburg General Hospital

A general revision has been undertaken to bring the whole book up to date and also to eliminate those sections which were not absolutely essential because it is important to prevent a book of this type from becoming too large. This new completely revised edition, with many excellent illustrations, is in two parts: Anatomy of the Normal and Anatomy of the Abnormal.

898 pages 779 illustrations £7·00 net

Our experience is something you can rely on

Remploy's contribution to Orthotics goes far beyond providing a comprehensive range of orthopaedic equipment.

Remploy are able to offer a unique measuring and fitting service for all their appliances and footwear, and have produced two orthopaedic brochures which are an invaluable aid to work in this field. Rely on this experience and send for literature, now.

Remploy

An exceptional name in Orthotics

Physical Examination of the Surgical Patient:

An Introduction to Clinical Surgery 4/e

By J. Engelbert Dunphy, M.D., Professor of Surgery, University of California School of Medicine, San Francisco, California, and Thomas W. Botsford, M.D., Associate Professor of Surgery, Harvard Medical School.

This fourth edition of **Physical Examination of the Surgical Patient** has undergone extensive revision, and introduces such new emphases as the problem orientated record and pathophysiologic mechanisms of surgical disease. Major changes to this edition appear in the elective examination of the breast, heart, abdomen, and the cancer patient; the emergency examination of the chest, abdomen, and the thermally injured patient. A more clear and concise listing of supplementary readings replaces the old bibliography, and many of the older figures have been replaced with new ones. A second colour plate of epidermal lesions has also been added.

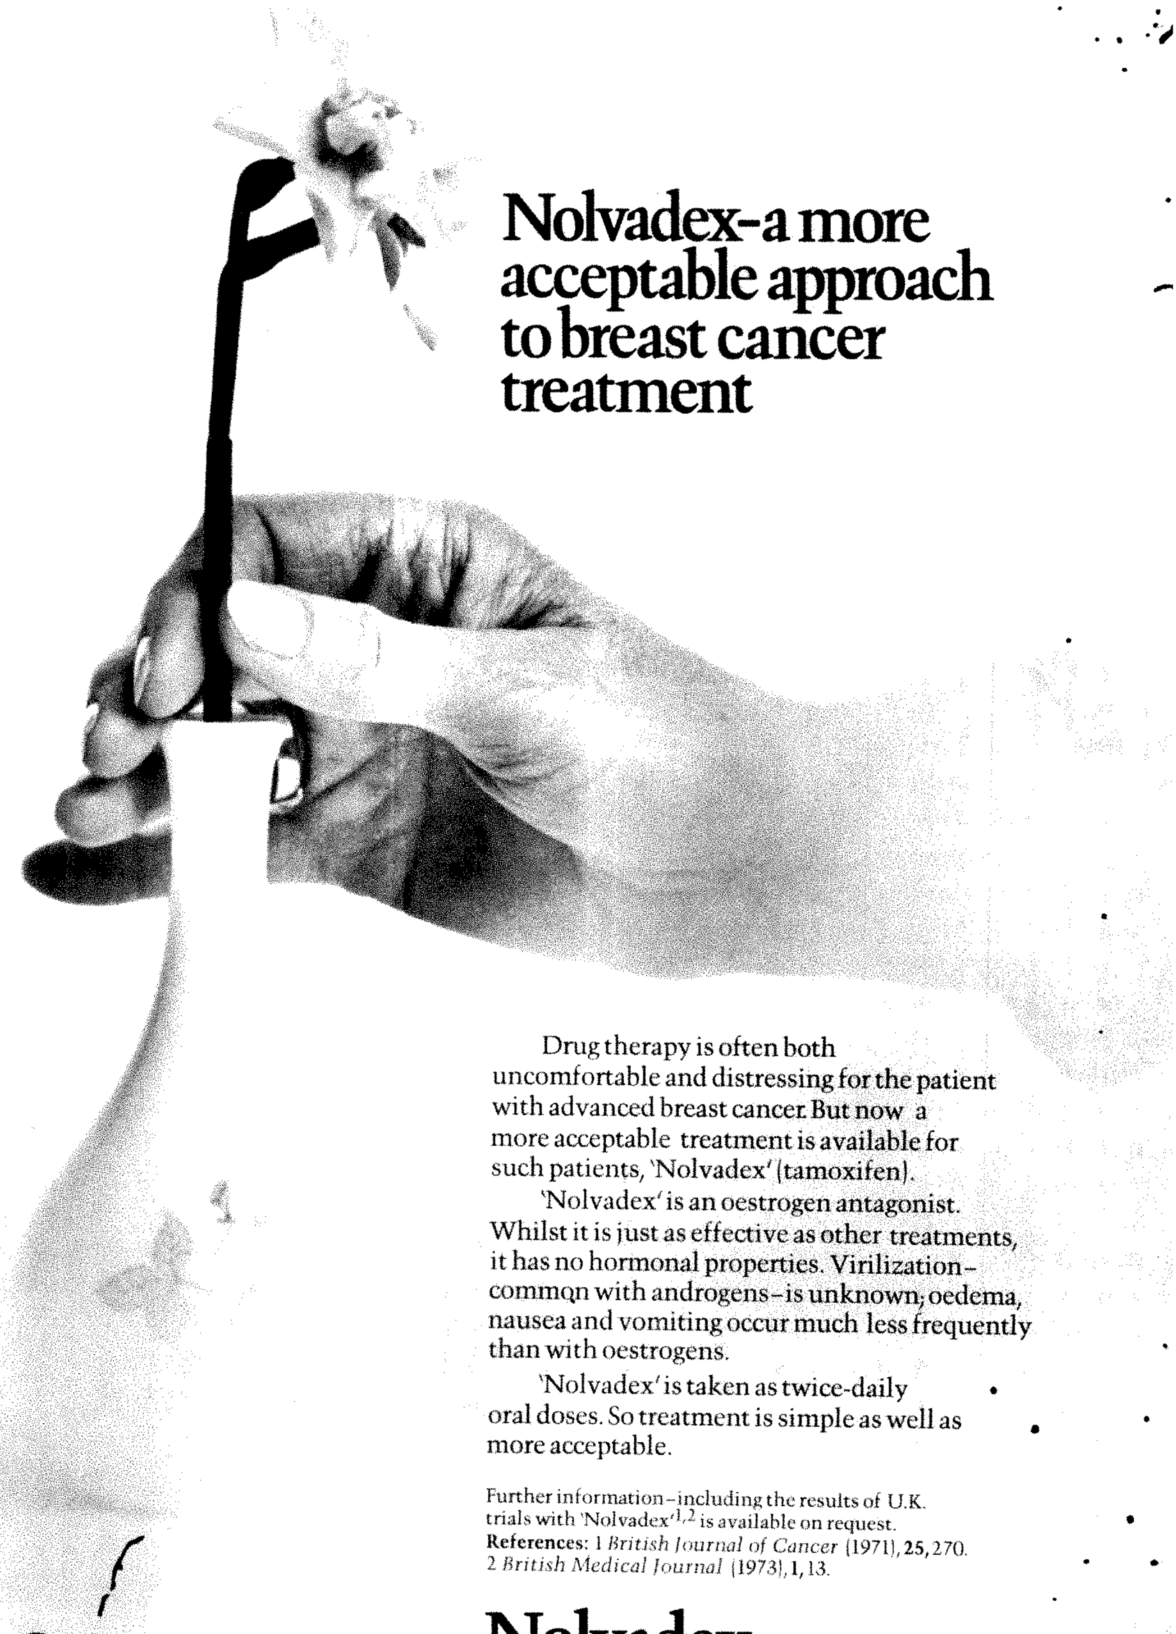
Nolvadex–a more acceptable approach to breast cancer treatment



Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

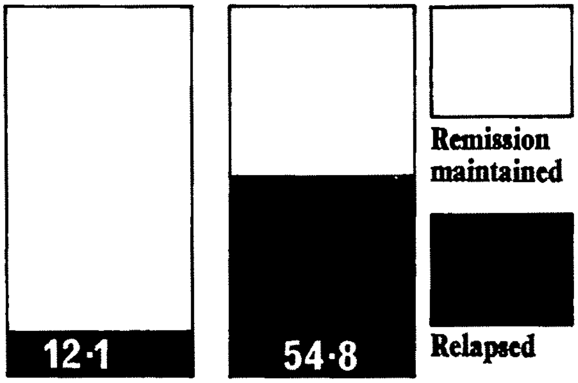
"It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects".[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford, are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be totally ineffective in reducing the number of recurrences of ulcerative colitis.

"Fortunately, Sulphasalazine tablets, 0.5 grams, 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely, since we do not know when, if ever, it can be safely stopped".[4]

"A striking difference in the relapse rate".



"The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine".[1] (Salazopyrin).

Salazopyrin (sulphasalazine) is available as the plain 0.5 g. tablet, 0.5 g. EN-tab and as an 0.5 g. suppository. Literature and detailed information on Salazopyrin are available on request.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original *illustrations* are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 61. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended. Leaflets giving further instructions are available on request.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

PRESENTATION OF STATISTICS

Authors are reminded that with the frequent use of statistical analysis in biological writing of all kinds it is desirable that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinical trials the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached.

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are more than two authors these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

The skill of the surgical team,
hours in the theatre, the most advanced
techniques in the world . . . and infection
can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

PATHOLOGY AND SURGERY OF THE SALIVARY GLANDS *by* **Jose Yoel**, *Rawson Hospital, Municipal Post Graduate School of Medicine, Buenos Aires, Argentina. Forewords by* **Pierre Cernea**, **John Conley**, **Hector Marino** *and* **S. L. Perzik.** The clarity of the text matter in this book reveals a deep knowledge of the topic under consideration, based on a long and eclectic experience. Anatomy, physiology, pathology and semiology, instrumental and radiological exploration, and medical and surgical treatment of salivary gland diseases have been assigned ample chapters in which every detail has been clearly covered. Clear anatomophysiologic sketches and magnificent illustrations of the operative stages clearly depict what the surgeon actually sees in the operative field. The author's punctilious attention to the surgery of tumoral processes does not lose sight of the possible morphological and functional repair of its consequences. Part I deals with fundamental concepts on embryology, histology, physiology and endocrinology and reviews the general pathology of the salivary glands and their diagnostic methods. Part II details the special pathology of the parotid gland and its excretory duct, the inflammatory condition, different salivary syndromes, lithiasis, primary and metastatic blastomas, as well as blastomas and pseudoblastomas of the parotid area. Parts III, IV and V are concerned with the special pathology of the submaxillary gland and its excretory duct, the special pathology of the sublingual gland, and the special pathology of the minor or accessory salivary glands. Each part contains a chapter on the surgical complications and sequelae. Operative techniques are shown in atlas form on the basis of photographs and notes taken by the artist present at the operation. Numerous photographs of patients as well as x-ray prints, including the reproduction of sialograms, contribute toward illustrating the subject matter. This treatise on the pathology and surgery of the salivary glands will find a wide acceptance since patients with salivary conditions are seen daily by clinicians and dentists, otolaryngologists, stomatologists, maxillofacial surgeons, plastic surgeons, neurologists and others. *'75, 1446 pp. (7 x 10), 2074 il. (7 in full color), 6 tables, $132.50*

REHABILITATION OF THE FACIALLY DISFIGURED: Prevention of Irreversible Psychic Trauma by Early Reconstruction *by* **J. J. Longacre**, *Univ. of Cincinnati, Cincinnati. (2 Contributors)* The author emphasizes the importance of early definitive care and early reconstruction of the maimed and mutilated. Congenital deformities, malignancies and accidents are all covered. *'73, 144 pp. (7 x 10), 384 il., 2 tables, $14.75*

THE SYSTEMIC MANIFESTATIONS OF INFLAMMATORY BOWEL DISEASE *edited by* **William M. Lukash** *and* **Raymond B. Johnson,** *both of the National Naval Medical Center, Bethesda, Maryland. (30 Contributors)* Current thoughts on the etiology and epidemiology of inflammatory bowel disease are reviewed in this book. Stressed are the numerous systemic manifestations of the disease including the intestinal complications of toxic megacolon, malignancy, extra-intestinal manifestations of liver disease, skin involvement, ocular complications, arthritis, metabolic-endocrine implications, hematologic sequelae and urological complications. By analyzing the pathological course of inflammatory bowel disease and the guidelines for proper diagnosis and treatment, this book will aid the physician in establishing earlier and more astute diagnoses and in instituting appropriate care. *'75, 368 pp., 92 il. (3 in color), 26 tables, $15.50*

COMMON DUCT STONES *by* **Frank Glenn**, *Cornell Univ. Medical College, Ithaca, New York.* Surgeons and internists who diagnose, manage and treat biliary tract disease will find this book valuable. The first section is devoted to the history of biliary tract disease and its recognition and the development of surgical procedures in its treatment. The sequelae of the disease, cholelithiasis, choledocholithiasis and liver disease are also discussed. Equipment is described that enables the performance of operative cholangiography before removal of the gallbladder. A discussion is provided of the reported successes and failures using solvents and instruments in removing retained calculi. Circumstances that may favor allowing demonstrated retained common duct calculi to remain unmolested are discussed as well. Developments in the diagnosis of biliary tract disease since Röntgen introduced the use of x-rays are reviewed. *'74, 148 pp., 22 il., 5 tables, $11.50*

INTERNATIONAL SYMPOSIUM ON MALIGNANT HYPERTHERMIA *edited by* **R. A. Gordon, Beverley A. Britt** *and* **Werner Kalow**, *all of the Univ. of Toronto, Toronto, Canada. (66 Contributors)* This volume presents discussions of the clinical recognition and management of this highly fatal disorder, recognizes hereditary and genetic basis of the trait and reports basic investigations of the mechanisms involved. *'73, 512 pp., 131 il., 55 tables, $22.50*

BOC Roberts Venous Flow Stimulator tackles the problem of d.v.t. where it starts

Every patient undergoing surgery is at risk from deep vein thrombosis. According to the Registrar General's reports, the incidence of death from d.v.t. – induced post-operative pulmonary embolism, is steeply rising.

It has been demonstrated* that the occurrence of deep vein thrombosis can be dramatically reduced by the application of intermittent calf compression per-operatively to prevent venous stasis. This procedure is, however, successful only when the pressure cycle conforms to blood flow dynamics. Critical considerations are:

- The duration and magnitude of the applied pressure.
- The timing of the pressure cycle to give vessels the optimum time to refill between compression phases.

Only the BOC Roberts Venous Flow Stimulator meets these criteria precisely and automatically. Clinical trials indicate that the apparatus can eliminate over 75% of cases of post-operative d.v.t. without the need for chemical intervention.

If you would like to know more about this equipment, please write or telephone us at the address below.

A new concept in surgical lighting
the DAYSTAR
major surgical light

Made in England by

DRAYTON CASTLE
SYBRON CORPORATION

Light Quality The **Daystar** provides cool shadow free colour corrected light giving maximum illumination and minimum heat in the surgical field.

An infinitely variable intensity controller means that you can regulate the level of light to suit your own requirements.

Positioning The **Daystar's** unrivalled ease of mobility puts the light where you want it and keeps it there without drift.

A snap-on autoclavable handle is provided to allow final surgical alignment where necessary.

Supplementary lights
An optional **Orbiter** attachment is available complete with its own intensity controller.

Track lights If you prefer track lighting the **Twinstar** combines **Daystar** quality light with twin track configuration.

Further information
Please complete and return the coupon for further details:

Please provide further details of the Daystar range of surgical lights by: (tick box)

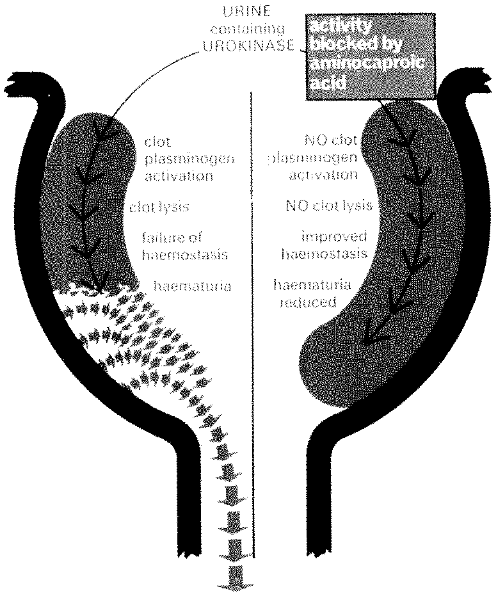
The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

Whither thyrotoxicosis?

W. MICHIE*

SUMMARY

For 30 years the thyrotoxic patient has been subjected to a plurality of treatments by surgery, radio-iodine and long term anti-thyroid drugs. These therapies have been accepted as complementary to the needs of the individual patient, without regard for long term results or the economic situation as it affects both patient and hospital services. In the context of surgical treatment which is now available, it is suggested that the advantages of operation over other therapies presage a reversion to surgery as the treatment of choice.

It was in the autumn of 1905 that Dr Hector Mackenzie, a physician of St Thomas's Hospital, wrote of the treatment of thyrotoxicosis, that when for a particular disease there were several remedies, none of these remedies would prove to be particularly efficacious. To this oft-quoted aphorism might be added another, that when the aetiology of a disease remains obscure, therapy may prove to be empirical, is liable to be uncertain and is unlikely to be convincing. Current thinking involves immunological and metabolic mechanisms. The former may be humoral from deposition of immunoglobulins on the basement membrane of the thyroid follicular cell (Werner et al., 1972) or cellular from defective lymphocytic immune surveillance (Volpé et al., 1972).

Metabolic factors have implicated thyroid autoregulation of iodine, both in excess and depletion, with consequent inability to modulate thyroid function and activity (Ingbar, 1972), and in this respect thyrotoxicosis has been ascribed to defective control of thyroid hormone synthesis with abnormal regulation of the relative proportions of T_3 and T_4. Practical evidence of the metabolic thesis was a more than twofold increase in the incidence of thyrotoxicosis in Tasmania following the addition of potassium iodate to bread as prophylaxis against endemic goitre (Connolly et al., 1970).

Modalities of treatment

Currently the thyrotoxic patient is treated by destructive therapy by radio-iodine or surgery or by long term surveillance on anti-thyroid drugs in the hope of eventual remission. Each method has its advantages, disadvantages and complications.

Anti-thyroid drug therapy

There is much to commend the concept of long term anti-thyroid drug treatment and the desire to protect from destructive therapy patients who might achieve spontaneous euthyroidism. In practice many difficulties are encountered. Anti-thyroid drugs do not interfere with the fundamental nature of the disease process (Furth et al., 1966), but merely inhibit the synthesis and release of thyroid hormones. Early relapse occurs in more than half the patients when drug therapy is withdrawn (Hershman et al., 1966), and in others relapse follows over the course of several years. The initial hope that successful remission might be predictable on the basis of suppression of radio-iodine uptake by tri-iodothyronine (Alexander et al., 1966) has not materialized (Lowry et al., 1971), and presently no method exists whereby remission can be foretold for the individual patient.

As a practical proposition, general acceptance of long term anti-thyroid drug therapy would prove to be a mammoth task. The incidence of thyrotoxicosis is not less than 1 per 5000 of the population annually (Furszyfer et al., 1970), equivalent to 10 000–11 000 new patients per year in the United Kingdom. On the assumption that a patient on long term therapy should be seen monthly for the first 3 months and 3-monthly thereafter, there would be 60 000 attendances at thyroid clinics in the first year, and with next year's accumulating harvest 100 000 attendances in the second year, and so on. While accepting that long term anti-thyroid drug therapy should be evaluated, there are grounds for regarding the evaluation as a reasearch programme for the well-staffed university department. Its universal adoption would leave room for doubt, for over 90 per cent of the clinical work in the United Kingdom is carried out in district hospitals which do not have the staff, medical or technical, to sustain a programme of this nature.

Thyrotoxicosis is in essence a disease of exacerbation and remission, and lifelong supervision becomes essential, for patients do tend to default from a programme which by its nature must have continuing review for many years. An undoubted risk is thyrocardiac disability in the late fifties and sixties, and most physicians must be familiar with the elderly patient whose fibrillation does not respond to digitalis therapy.

---

* Aberdeen Royal Infirmary.

Radio-iodine therapy

Radio-iodine therapy has undoubted appeal. It is inexpensive and easy to administer, and the initial fear of neoplastic degeneration has not materialized (Saenger et al., 1968), though doubts have been expressed on possible long term effects in children (Starr et al., 1964). Genetic defects have not become apparent (Hayek et al., 1970), though gene mutation, being recessive, is not expressed in the first generation and must await the verdict of several generations.

Radio-iodine exerts its effect by interference with the replicative mechanism of the thyroid follicular cell (Greig, 1965), with the implication that the end point may be hypothyroidism in all patients if followed for sufficient length of time. The rate of interference is unpredictable, and therein lies the dual problem of slow rate of thyroid control and the progressive risk of thyroid failure. In general, however, the incidence of hypothyroidism increases *pari passu* with the dose of radio-iodine administered, and even with conventional doses hypothyroid rates of 80 per cent are quoted after 15 years (Greig, 1973). The hope that low energy, short range radiation from ^{125}I (Greig et al., 1970) would diminish interference with the nucleus of the thyroid follicular cell has not been fulfilled. Hypothyroid rates are similar to those following ^{131}I therapy (McDougall et al., 1971; Bremner et al., 1973).

Irrespective of the isotope used and the dosage régime adopted, a progressive and relentless hypothyroidism would seem inevitable. This is not without hazard. Overt hypothyroidism can readily be detected by routine tests of thyroid function, but forms less clinically obvious exist whose detection rests upon the evidence of clinical improvement from thyroxine administration or from the use of more sophisticated techniques (Hedley et al., 1971a; Evered et al., 1975). The number of patients treated each year may remain relatively constant, but the total number accumulates and becomes part of an increasing clinical burden. This can in large measure be solved by the adoption of an annual follow-up programme controlled by a computer-based register such as now operates in the major centres of Scotland (Hedley et al., 1970a). Without such help hazards continue. For the younger patient with persisting hypothyroidism there is a risk of developing ischaemic heart disease (Bastenie et al., 1971), and for old people who tend to forget their medicaments there is the risk of morbidity from hypothermia.

Thyroidectomy

Thyroidectomy also has its complications, some of which derive from the surgical procedure and others develop during postoperative follow-up. For some both potential risk and incidence have been overemphasized in the past; for others potential hazards have not received sufficient emphasis in the current literature.

Mortality

The mortality is negligible and may be nil in established thyroid clinics. In a personal series of 1500 thyrotoxic patients 1 death was attributable to surgery. This patient had anaesthetic complications during operation, following which she became decerebrate and died several months later.

Wound infection

Wound infection rarely occurs, presumably by reason of hyperdynamic circulation and increased vascularity in the operation area.

Wound haemorrhage

With reasonable care wound haemorrhage should be negligible. It may be present in either of two locations: above or below the strap muscles. The former is more frequently seen and can be circumvented if bleeding from the anterior jugular plexus of veins is avoided. The latter is rarely seen but is potentially dangerous. It derives from inadequate ligature of a major vessel in one of the lobes; the haematoma develops rapidly, lies laterally in the neck and must be evacuated quickly.

Nerve injuries

Potential injuries are several, and taken in chronological order of occurrence at operation four nerves are at risk.

Cutaneous nerves may be avoided by careful raising of the upper skin flap, when the nerve may be seen lying immediately deep to platysma. Section is followed by loss of sensation under the chin, which becomes a matter of inconvenience to the shaving male.

Superior laryngeal nerve: Of the nerves which may be involved in thyroid surgery, the superior laryngeal nerve is most at risk, though the danger remains the least publicized. It stems from the vagus below the ganglion nodosum, descends in company with the superior thyroid artery and soon divides into internal and external branches. The larger internal branch pierces the thyrohyoid membrane and supplies motor fibres to the intrinsic muscles of the larynx and mucosal sensation above vocal cord level. The external is of fine calibre and proceeds in medial proximity to the superior thyroid artery to supply the cricothyroid muscle. Though normally it lies outwith the cervical fascial investment of the superior pole, it may in 20 per cent of patients pass between the branches of the superior thyroid artery as they disperse on the superior pole (Moosman and De Weese, 1968). Interference with the cricothyroid muscle or its innervation decreases vocal cord tension. The voice becomes harsh, loses volume and pitch and tires easily. On laryngoscopy the cord becomes crenated and thickened and an ivory hue replaces normal pearly whiteness. Cord movement remains unimpaired.

The internal branch is at risk where traction is employed to bring down an enlarged superior pole which lodges behind the larynx. When the entire superior laryngeal nerve is involved, swallowing, particularly of fluids, is additionally disturbed (Hirzel, 1958). Fluids seep into the larynx by day and saliva at night. Persisting coughing and spluttering ensue and pneumonitis may supervene. The patient gradually adopts trick drinking habits by holding the chin forward and tilting the head to one side. By reason of its more fortunate anatomical location, internal laryngeal nerve involvement is comparatively rare, but voice changes from external laryngeal nerve interference may occur in varying degree in 20 per cent or more of patients.

Cervical sympathetic chain: Damage to the cervical sympathetic chain is not infrequent in malignant goitres, but is one of the rarer complications of thyroidectomy for thyrotoxicosis. The author has seen this in 2 patients. Injury occurs during ligation of the inferior thyroid artery, and myosis, ptosis and enophthalmos ensue. Though the lesion is described as Horner's syndrome, the vascular symptoms which form part of this syndrome are generally absent (Smith and Murley, 1965). It may be that the autonomic fibres subserving facial sweating synapse more proximally than do those from the superior cervical ganglion, which pass via the internal carotid artery plexus to the ophthalmic division of the trigeminal and the nasociliary nerves to supply the dilator pupillae muscle.

Recurrent laryngeal nerve: Injury is widely publicized, and has a recorded incidence which varies from 3·9 per cent of the nerves exposed to risk (Gisselsson, 1949) to nil (Wade, 1961). In the author's series permanent paresis was less than 0·5 per cent of the nerves at risk. It is more often seen in thyroidectomy for non-toxic goitre when the nerve may be displaced laterally from the trachea and oesophagus by colloid cyst intrusion. Routine exposure is believed by some to reduce the incidence of nerve injury (Lahey, 1938; Riddell, 1970), though this is not universal practice (Michie, 1970). Paresis is frequently temporary and may develop postoperatively, but if a trusted anaesthetist has recorded vocal cord movement by direct laryngoscopy at the end of the operation it can be assumed that full recovery will eventuate.

The results of nerve suture carried out at the time of initial operation or by a subsequent procedure are considered satisfactory by some (Siribodhi et al., 1963; Doyle et al., 1967), but inadequate by others (Lahey, 1944; Murakami and Kinchner, 1971), principally by reason of axonal confusion in the regenerating nerve with random re-innervation of antagonistic adductor and abductor laryngeal musculature (Boles and Fritzell, 1969).

Bilateral nerve injury, though extremely rare in thyroid clinics, is a catastrophe. Tracheostomy must follow its detection and must be maintained until laryngeal function can be restored by procedures designed to re-establish the glottic aperture. This may be achieved by arytaenoidopexy or arytaenoidectomy. In the former the arytaenoid cartilage is mobilized submucously via an external approach through the inferior constrictor muscle and maintained in a lateral position by suture to the omohyoid (King and Gregg, 1948). In the latter the arytaenoid is resected submucously by endoscopic procedure (Thornell, 1950).

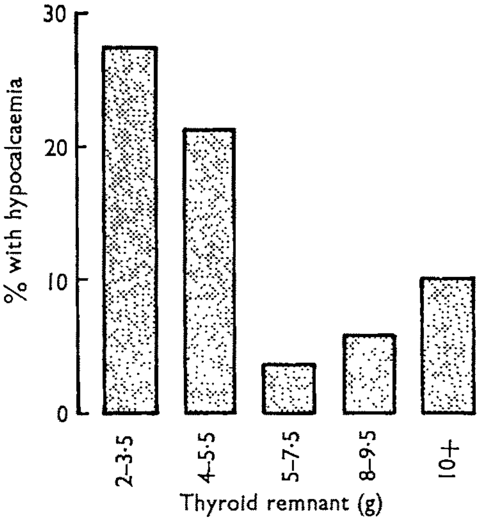

Fig. 1. Change of risk of postoperative transient hypocalcaemia with estimated size of remnant after partial thyroidectomy. (Reproduced from Michie, 1970.)

Hypocalcaemia

The hypothesis that parathyroid damage or infarction explains the hypocalcaemic and tetanic manifestations which occasionally follow thyroidectomy for thyrotoxicosis is widely acclaimed (Lachmann, 1941; Davis et al., 1961; Riddell, 1962), but cannot be accepted on present clinical, biochemical and experimental evidence. Graves' disease, particularly untreated and of prolonged duration, induces gross skeletal decalcification (von Recklinghausen, 1891). Thyroid hormones act on the bone cell, accelerating turnover rate, with increasing calcium loss in the urine and faeces, and culminating in a state of hungry bones. When partial thyroidectomy is performed leaving substantial remnants, the risk of hypocalcaemia is minimal, but after radical thyroidectomy, particularly in the young florid thyrotoxic with active bone metabolism, the risk is greatly enhanced (*Fig.* 1).

Hypocalcaemic symptoms appear within a few hours of operation and are likely to persist until the negative calcium balance has been corrected by adequate calcium supplement (Michie et al., 1971). When the calcium balance has been restored, and the bones are no longer hungry, hypocalcaemic manifestations of paraesthesia and tetany disappear and calcium homeostasis is maintained without further supplement. This sequence of events cannot be explained on the basis of damage to the parathyroids or their blood supply. When total thyroparathyroidectomy is performed, as may happen in laryngopharyngectomy, hypocalcaemic

Table I: REPORTED INCIDENCE OF HYPOTHYROIDISM FOLLOWING THYROIDECTOMY FOR THYROTOXICOSIS

Author	Incidence of hypothyroidism (%)
Pemberton (1930)	2·9
Riddell (1961)	3·3
Cattell (1949)	4·5
Bartels (1952)	7·3
Murley and Rigg (1968)	7·5
Taylor and Painter (1962)	9·3
Goadby (1937)	18·0
Thomson et al. (1930)	19·5
Hershman (1966)	29·7
Hedley et al. (1970b)	35·6
Cassidy (1962)	38·0
Nofal et al. (1966)	42·0
Beahrs and Sakulsky (1968)	48·0

Table II: INCIDENCE OF HYPOTHYROIDISM IN RELATION TO TOTAL GLAND MASS

Gland weight (g):	Hypothyroid rate (%):
10–29	42
30–49	51
50–69	46
70–99	31
>100	35

manifestations are delayed until 48–60 hours after operation; in contrast, significant hypocalcaemic symptoms which follow thyroidectomy for thyrotoxicosis are apparent within a few hours and invariably within 24 hours of operation. Furthermore, hypocalcaemia is extremely rare (Murley and Peters, 1961) or may not be seen (Michie et al., 1971) after thyroidectomy for non-toxic goitre, even where resection has been severe.

Experimentally, two or more parathyroids can be removed without hypocalcaemic symptoms (Welsh, 1898; Sanderson et al., 1960), and though the parathyroids are known to be at risk in thyroid surgery (Murley and Peters, 1961), interference sufficient to produce hypocalcaemia would seem improbable. Further supportive evidence comes from the surgery of parathyroid adenoma. Accepted surgical policy in many centres is to identify each of the remaining parathyroids histologically, and since adequate biopsy entails removal of approximately half the gland, the patient is left with the equivalent of one and a half parathyroids. Despite this, and excluding parathyroid tumours associated with osteitis fibrosa cystica, abnormal serum calcium values following operation are unusual.

Available evidence would therefore suggest that the term 'postoperative hypoparathyroidism' with its implication of parathyroid damage or interference is misleading and without factual evidence, and that it should be discarded in favour of 'postoperative hypocalcaemia', which is largely self-rectifying when calcium balance is restored.

Recurrent thyrotoxicosis

Provided that adequate thyroidectomy has been performed, the recurrence rate is around 6 per cent (Hedley et al., 1970b), and recurrence may be seen at any stage in the life of the postoperative thyrotoxic patient. It usually appears in the early postoperative years, and failure to achieve euthyroidism after operation is not unknown and has occurred twice in the author's series. On the other hand, recurrence may be delayed for 20 years or more after surgery.

The mechanism of recurrent thyrotoxicosis is unknown but continuing failure of T_3 suppression of ^{131}I uptake suggests the presence of an extrapituitary stimulator. In a retrospective study of patients treated by subtotal thyroidectomy between 2 and 21 years previously (Hedley et al., 1971b), 83 per cent showed complete suppression while none of the patients with recurrent thyrotoxicosis suppressed. In a recent study (Mukhtar et al., 1975) thyroid-stimulating immunoglobulins were detected in the serum of all patients with untreated Graves' disease and following operation were found to disappear in 83 per cent and persist in 17 per cent, a figure identical with the number of patients who failed to suppress (Hedley et al., 1971b). These results suggest that thyroid-stimulating immunoglobulins may play a role in the pathogenesis of recurrent thyrotoxicosis.

Recurrent thyrotoxicosis responds to radio-iodine but not to further surgery. In one recorded series 10 out of 10 patients (McLarty et al., 1969) and in another 5 out of 6 patients (Hedley et al., 1970b) had further recurrence after two or more thyroidectomies.

Hypothyroidism

Without doubt hypothyroidism is the major complication of thyroidectomy for thyrotoxicosis. The recorded incidence (*Table I*) has varied from 2·9 per cent (Pemberton, 1930) to 48 per cent (Beahrs and Sakulsky, 1968). The higher figures have, by and large, been recorded in the past 10–15 years, and probably represent an increased awareness of the clinical problem and a more critical evaluation of postoperative thyroid status. Historical evidence from the turn of the century suggests that the higher figures may be more realistic (Williamson, 1896; Mackenzie, 1905; Sattler, 1908; Campbell, 1921). Approximately 20 per cent of untreated patients died acutely in crisis, while 40 per cent pursued a chronic course of exacerbation and remission into thyrocardiac disability. Some 30–40 per cent ultimately improved spontaneously, and while some remained euthyroid, others lapsed into hypothyroidism over the course of several years (Baldwin, 1895; Campbell-Gowan, 1895; Sattler, 1908). It would appear, therefore, that in some thyrotoxic patients there is a naturally progressive thyroid impairment leading to decreased reserves of thyroid function or frank failure, and it may be that in these patients surgery merely accelerates the natural course of the disease, compressing the events of many years into a matter of weeks or a few months.

In an attempt to define the factors responsible for hypothyroidism, we made a study of thyrotoxic patients operated upon during the years 1965–72 (Michie et al., 1972; Pegg et al., 1973). The factors examined were in preoperative preparation, surgical management and postoperative behaviour. It became clear that several factors did not influence postoperative thyroid status. The duration of anti-thyroid drug therapy varied from 4 weeks to several years, as determined by the physicians who supervised the preoperative care of the patient. No correlation was found between postoperative hypothyroidism and the duration of therapy, or the amount of anti-thyroid drugs prescribed. Despite considerable variation in the size of the glands (*Table II*), no relationship between total gland mass and hypothyroidism could be demonstrated. It is generally accepted that higher anti-cytoplasmic (but not anti-thyroglobulin) antibody responses indicate an increased risk of postoperative hypothyroidism (Irvine et al., 1962; Van Welsum et al., 1974); formerly we were unable to confirm this, but in recent years we have found that as the titre of anticytoplasmic antibody increased from negative to strongly positive, the number of euthyroid patients decreased by an additional 14 per cent ($P<0{\cdot}001$) and anti-thyroglobulin antibody by 4 per cent ($P<0{\cdot}01$). Even so, though the trend is marked, the relative size of the association remains small.

The significance factor which determined the behaviour of a group of patients after partial thyroidectomy was the size of the thyroid remnant left at operation (*Table III*). Remnants of less than 4 g carried the highest hypothyroid rate, whereas those of 10 g or more carried the lowest ($P<0{\cdot}001$). It must be emphasized, however, that size alone is not the only criterion, for with a remnant of 4 g or less there was a 36 per cent incidence of euthyroidism, while with a remnant of 10 g or more hypothyroidism occurred in 19 per cent of patients.

When remnant weights are charted against percentage hypothyroidism, there would appear to be two relevant indices. Hypothyroidism decreased by about 10 per cent/g as remnant weight increased to 7·5 g, and there was a similar fall thereafter of 2 per cent/g as remnants increased to 16 g (*Fig.* 2). Exponential interpretation of this graph would suggest that there is a group of patients, comprising some 15 per cent, who might develop hypothyroidism irrespective of remnant size. It would seem possible that the patients in this group are precisely the thyrotoxic patients who at the turn of the century were capable of achieving euthyroidism and later hypothyroidism without any form of therapy.

The surgeon, like his counterpart the physician in nuclear medicine, must therefore accept a measure of post-treatment hypothyroidism, and for the surgeon this figure is unlikely to be less than 25 per cent (*Table IV*). Whichever the method of treatment, there is a clinical and ethical responsibility for the continuing supervision of these patients. It was the author's practice to estimate protein-bound ^{127}I levels at 1 and 4 months after operation, and yearly thereafter, until the services of a computer-assisted register came into operation (Hedley et al., 1970a). From a study of these patients a distinctive pattern has emerged (*Table V*). Where both the 1-month and 4-month levels are below 4 μg per cent the incidence of hypothyroidism is 77 per cent. Where one of the values is below 4 μg per cent the incidence of hypothyroidism is around 20 per cent, but a rising value holds a more favourable prognosis than a falling one. Where both levels are above 4 μg per cent all the patients are euthyroid, and the risk of developing hypothyroidism subsequently is negligible.

The definition of postoperative hypothyroidism at an early date is in accord with the experience of others (Olsen et al., 1970; Caswell and Maier, 1972), and may suggest that when a rising incidence is recorded over several years (Nofal et al., 1966; Gough and Neill, 1974), a lower index of clinical suspicion of

Table VI: PREPARATION OF THE THYROTOXIC PATIENT FOR SURGERY

Group	Treatment	No. of cases
1	Carbimazole and Lugol's iodine	42
	Carbimazole, propranolol and Lugol's iodine	69
2	Propranolol and Lugol's iodine	51
3	Propanolol alone	47

postoperative hypothyroidism may have been accepted during the first postoperative year.

Provided that a remnant of 8–9 g is left, postoperative thyrotoxic patients can be offered a group prediction of 70–75 per cent euthyroidism, and the status of the individual patient can with reasonable assurance be defined within a year. This is a matter of some importance for the busy surgeon for whom the facilities of a computer-assisted register may not be available. Although ideally all patients subjected to surgery merit lifelong supervision, the surgeon can concentrate his attention on the 25–30 per cent of patients whose early postoperative protein-bound ^{127}I levels have been less than 4 μg per cent. In this respect the surgeon is at an advantage over his medical colleague.

Beta-adrenergic blockade in thyrotoxicosis

Further advantages to the surgically treated patient may accrue from pretreatment by beta-adrenergic blockade. For many years the similarity between the clinical features of hyperthyroidism and increased sympathetic activity has been recognized. Sympathetic blockade is not a new concept. Early attempts were surgical, initially by section of the cervical sympathetic chain (Jaboulay, 1897), and later by adrenalectomy or adrenal denervation (Crile, 1929). There followed the use of several pharmacological agents to reduce sympathetic overactivity: reserpine (Buchanan et al., 1959), guanethidine (Waldstein et al., 1964) and alpha-methyldopa (Theilen et al., 1963). Later came the first beta-blocker, pronathalol, which was discarded because of adverse reactions (Wilson et al., 1964), but with the introduction of propranol, beta-blockade became a practical proposition (Rowlands et al., 1965; Turner et al., 1965). Initially, it was used in the treatment of thyrotoxic crisis and later as an adjuvant to radio-iodine therapy. More recently, propranol has been found of value in the surgical management of thyrotoxicosis (Lee et al., 1973; Michie et al., 1974).

It was in 1970 that we decided to investigate the use of propranolol in the surgery of thyrotoxicosis, and since then we have employed it, either alone or in combination with other drugs, in a series of patients. Our approach has been cautious, and initially we used it in combination with carbimazole and Lugol's iodine (iodine with potassium iodide), later replacing carbimazole with propranolol and finally using propranolol as the sole preoperative agent. Though these stages inevitably overlapped we were able to study the behaviour of patients prepared for operation with propranolol, both with and without Lugol's iodine, and to compare them with a similar group conventionally prepared with carbimazole and iodine. There were approximately 40–50 patients in each group (*Table VI*).

Pulse rate and blood pressure were monitored during hospitalization, and biochemical records of calcium, protein-bound ^{127}I, serum alkaline phosphatase and total protein were made when the patient was first seen, immediately before and after operation, and at 24 and 48 hours and at 1 and 4 months after operation.

Pulse rate was on average 10 beats per minute slower in the propranolol groups (*Fig.* 3). Blood pressure was similar in all the groups except that the mean systolic reading at the end of operation was 10 mm Hg lower in the propranolol patients (*Fig.* 4). Serum calcium corrected for serum protein levels (Dent, 1962) was the same when first seen but higher through operation in the propranolol groups, though these differences were not apparent at 1 and 4 months after operation (*Fig.* 5). In general, serum alkaline phosphatase levels showed a parallel reduction in the three groups, excepting the concentration at 1 month after operation, which was higher in the propranolol patients (*Fig.* 6). Both the serum calcium and serum alkaline phosphatase levels are in harmony with the thesis of a healing thyrotoxic, osteodystrophy occurring at a later phase in the propranolol groups.

Serum protein-bound ^{127}I values were the same at the initial examination but were significantly higher in propranolol-pretreated patients while they remained

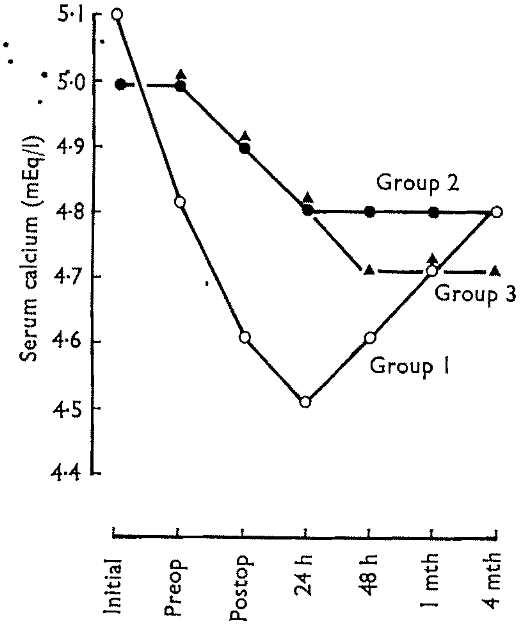

Fig. 5. Comparison of serum calcium values in relation to preoperative treatment. (Reproduced from Michie et al., 1974.)

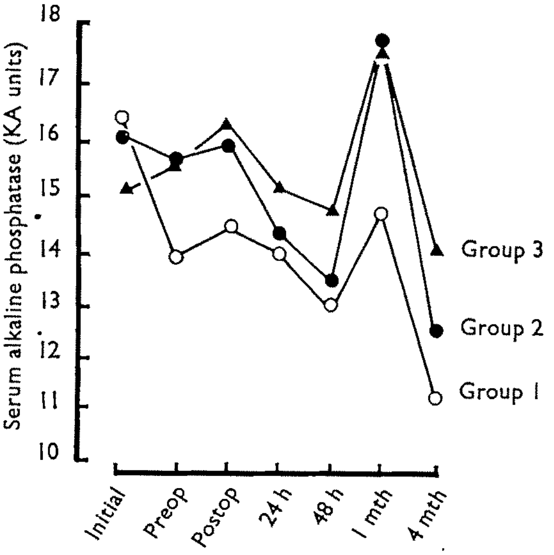

Fig. 6. Comparison of serum alkaline phosphatase values in relation to preoperative treatment. (Reproduced from Michie et al., 1974.)

Table VII: LEVELS OF SIGNIFICANCE OF PROTEIN-BOUND ^{127}I AT 1 AND 4 MONTHS AFTER OPERATION ACCORDING TO PREOPERATIVE THERAPY

Comparison	Time of protein-bound ^{127}I estimation 1 mth	4 mth
Carbimazole and iodine versus propranolol and iodine	Not significant	Not significant
Carbimazole and iodine versus propranolol	$P = 0{\cdot}005$	$P = 0{\cdot}005$
Propranolol and iodine versus propranolol	$P = 0{\cdot}02$	$P = 0{\cdot}005$

Table VIII: COMPARISON OF PATIENTS PREPARED FOR OPERATION WITH CARBIMAZOLE AND LUGOL'S IODINE, AND PROPRANOLOL WITH AND WITHOUT LUGOL'S IODINE

Treatment	Mean no. of outpatient attendances	Mean duration of treatment (d)
Carbimazole and Lugol's iodine	9	143
Propranolol and Lugol's iodine	4	46
Propranolol alone	3	25

in hospital (*Fig. 7*). By the seventh postoperative day the protein-bound ^{127}I levels had returned to normal, but fell considerably lower at 1 and 4 months after operation. The size of the decrease is most significant in the patients treated with propranolol alone (*Table VII*). The reason might be that with Lugol's solution, iodine is readily available for iodoprotein synthesis in the thyroid follicular cell, but a more likely explanation is that with propranolol alone, patients lack the stimulus which carbimazole and iodine give in promoting the resumption of thyrotropic control of thyroxine synthesis. In practical terms, while normal protein-bound ^{127}I values are possible at 1 and 4 months after operation in the carbimazole-prepared patient, the same may not be achieved until 12–15 months after operation and even longer with propranolol alone.

If a new form of therapy is to merit consideration it must offer significant advantages over current methods of treatment. This can be measured only in the wide context of a comparison of all three methods of treatment. Long term anti-thyroid drug therapy is labour-intensive and runs a potential risk of late recurrence with thyrocardiac damage. In the destructive therapies, either by radio-iodine or by surgery, the problem is that of hypothyroidism. Following radio-iodine, potential hypothyroidism in all patients cannot be gainsaid. Surgery, with 25–30 per cent hypothyroidism, might be regarded as the least bad bet, and though there is an ethical responsibility for continuing supervision, the fate of the remaining 70–75 per cent, recurrent thyrotoxicosis excluded, should be secure.

The aims of treatment should be to secure the best result, with maximum safety, at the least economic cost to patient and hospital, and with the greater convenience to the patient. We believe that the use of propranolol achieves these aims. The mean number of outpatient attendances and the duration of treatment for different preoperative therapies are detailed in *Table VIII*. Admittedly, the mean duration for carbimazole at 314 days includes patients who failed to achieve remission after several months' therapy, while in patients prepared with surgery in mind from the time of diagnosis the mean duration was 82 days. Equally, the present position is understated in that preoperative preparation with propranolol can be limited to 5–6 days, and admission to hospital for surgery to 3–4 days, so that the whole episode of treatment for thyrotoxic illness can be reduced to 10 days. Hence, when physician and surgeon jointly agree that for an individual patient surgery is the method of choice, the sooner it is completed, the better it is received by, and the better for, the patient. In these days of economic stringency when both husband and wife must strive to maintain home and family, it is a matter of no mean import that a hospital procedure be reduced to a minimum.

For the surgeon also there are advantages. The propranolol-prepared gland is more pliable and mobilizes easily. It is less friable and bleeds less. Thyroidectomy can be achieved with blood loss as small as 15–20 ml, and the technical dangers of surgery are thereby considerably reduced.

The use of propranolol without iodine is open to criticism on the grounds that the patient remains exposed to high circulating levels of thyroid hormones, and is thereby ill-equipped to respond to situations of stress such as bleeding or cardiac infarction during operation. Preoperative Lugol's iodine promotes the acute Wolff–Chaikoff effect of reduced thyroid hormone synthesis with changes similar to those produced by conventional anti-thyroid drugs (Wolff and Chaikoff, 1948). Though 1 patient recently did have a small cardiac infarct shortly after operation from which she made an uneventful recovery, our impression has been that in general the behaviour of patients prepared with propranolol, with or without Lugol's iodine, has not been different before, during or after operation from those prepared with carbimazole.

Beta-adrenergic blockade appears to be a safe procedure provided that certain rules are observed. It cannot be used in patients with obstructive airways disease or with a past history of asthma. It is ineffective when the patient is under treatment with antidepressant drugs such as Tryptizol. Dosage must be carefully observed, and if there is doubt about the patient's co-operation or reliability she should be admitted to hospital for preoperative therapy. In particular, the immediate preoperative dose must not be overlooked, for patients can quickly emerge from beta-blockade.

The advantages and disadvantages of treatment by different disciplines are difficult to define and quantify, but it may not be without significance that recent trends in the United States have revealed an increase in the percentage of patients with Graves' disease who have been treated surgically (Schlicke, 1974). This has been ascribed to growing disenchantment with conservative treatment. While the swing to radio-iodine therapy in the United Kingdom has never been so pronounced as in the United States, where choice of treatment may to greater degree be influenced by economic costs, it may be that in the next few years there will be an increasing advocacy of surgery for the thyrotoxic patient.

Surgical treatment of thyrotoxicosis: results of 272 operations with special reference to preoperative treatment with anti-thyroid drugs and L-thyroxine

PETER HEIMANN AND JAN MARTINSON*

SUMMARY

From 1959 to 1970, 272 operations for thyrotoxicosis were performed. Most of the patients received anti-thyroid drugs and thyroid hormones preoperatively. The patients were continuously followed up. The primary results with low morbidity and no mortality as well as the long term results with a low rate of recurrence and a relatively high incidence of thyroid substitution are discussed. A safe and effective programme for surgical treatment of thyrotoxicosis is described. Anti-thyroid drugs and thyroid hormones should be administered as the method of choice in preparing these patients for surgery.

THE results of surgical treatment of thyrotoxicosis have improved dramatically during the past 10–15 years. One reason is that there are now three different forms of treatment: anti-thyroid drugs, radio-iodine therapy and surgery. Each treatment can be used for a different group of patients and therefore a better selection of patients for surgical treatment can be made. Another reason is that patients undergoing surgery after preoperative treatment with anti-thyroid drugs *and* L-thyroxine are easier to operate on, with a small operative morbidity and without risk of a post-operative thyrotoxic crisis. The patient is euthyroid, the thyroid is empty of thyroxine (due to inhibition of synthesis by anti-thyroid drugs) and the gland is unstimulated (due to the TSH-inhibiting effect of thyroxine therapy). The combination of anti-thyroid drugs and thyroxine was first introduced by Fraser and Wilkinson in 1953. Bergfelt et al. used this treatment preoperatively in 1961. The effect of such treatment on the thyroid has been studied by various methods, e.g. histological studies (Eggen and Seljelid, 1973) and electron microscopy studies (Heimann 1966, 1967), which have shown that the histological picture of the adequately pretreated gland is very similar to that of the normal gland or the non-toxic goitre. In this paper we report our clinical experience and the results of surgical treatment of thyrotoxicosis.

Patients

All the patients with thyrotoxicosis presenting to the Department of Surgery II, Sahlgrenska Hospital, Göteborg, during the period from 1 January 1959 to 31 December 1970 are included. The series consists of 395 patients with thyrotoxicosis; 271 were treated surgically and 124 were treated medically or with radio-iodine, according to the principles of selection shown in *Fig.* 1. Of the 271 surgically treated patients, 48 were male and 223 female (ratio 1 : 5). The age distribution and different histological diagnoses are shown in *Fig.* 2. Of the operations, 258 were primary and 14 were reoperations (one of our patients was operated on twice).

Methods

Preoperative diagnostic programme

Thyroid function was assessed from the serum protein-bound iodine and the T_3 test. In difficult cases the ^{131}I uptake curve and/or the T_3 inhibition test were used.

In cases with goitre X-rays of the neck and thorax were carried out. Scintigraphy was always performed in cases with nodular goitre and in those with adenoma.

For assessment of the parathyroid function estimations of serum calcium, phosphorus, albumin and creatinine were made.

The recurrent laryngeal nerve was studied by laryngoscopy. Electrocardiogram, chest X-ray, haemoglobin and blood sedimentation rate were performed routinely.

The most important parts of the preoperative investigation are obtaining a complete history of the disease and evaluation of the clinical status. In cases with exophthalmos an ophthalmologist should be involved. All these investigations can be performed on an outpatient basis. Only patients with severe thyrotoxicosis or other complicating disease need hospitalization.

Preoperative treatment

This was performed according to the following principles:

1. The patient was started on an anti-thyroid drug, carbimazole (or methimazole) 10 mg q.i.d. or propylthiouracil 100 mg q.i.d.

2. If the thyrotoxic symptoms were severe and/or the goitre large it was often necessary to give a larger dosage. In most cases 10 mg six times a day (100 mg six times a day for propylthiouracil) were sufficient. If still larger doses were needed the patient was treated in hospital. All patients can be made euthyroid with this treatment if adequate dosage is given over a sufficient period of time.

Primary treatment
Initially, anti-thyroid drugs in all cases
Addition of thyroid hormone
Radio-iodine
Surgery
Temporary addition of anti-thyroid drugs
Indications
Most serious cases aged 20–50 years
Nodular goitre
Intrathoracic goitre
Toxic adenoma
Mild cases
Small or no goitre
Childhood
Doubtful cases
Cases aged >50
Contraindications for surgery

Surgical treatment in euthyroid phase 20

Fig. 3. Alternative treatment of 35 patients who developed side effects with the initial anti-thyroid drug.

We did not perform repeated white blood cell counts. All the patients received written information about the side effects of the preparation used and were told to contact their doctor or the hospital as soon as they noticed any symptoms.

3. When the patient became euthyroid—in most cases after 6–8 weeks—the dosage of the anti-thyroid drug was reduced to 5 mg q.i.d. for carbimazole (or methimazole) or 50 mg q.i.d. for propylthiouracil. The patient was told that it was necessary to continue with this dosage until the day of operation.

4. In addition to this reduced dosage of anti-thyroid drug the patient also received thyroxine (L-thyroxine) 0·20 mg every morning. (It is also possible to give tri-iodothyronine 0·02 mg t.d.s. or q.i.d.) Older patients with nodular goitre or very small (< 50 kg) patients received 0·15 mg thyroxine once daily. This combined treatment was continued for at least 4 weeks, and it was often advisable to continue it for longer. Most of our patients were treated for a varying period of time (from 1 to 6 months). Thus it was possible to operate on the patient at a time suitable for the patient, surgeon and hospital.

Carbimazole was the most frequently used anti-thyroid drug (148 patients), methimazole was used in 73 cases and propylthiouracil in 27. If preoperative treatment had been started elsewhere, we always continued with the drug used initially.

Not all the patients were pretreated with anti-thyroid drugs and thyroxine, because of our electron microscopy study, in which different methods of treatment were compared (Heimann, 1966). Most of the toxic adenomas were operated on without preoperative treatment. Some patients with complications caused by the preoperative treatment were transferred to another group (*Fig.* 3).

Operative technique

All the patients were operated on under general endotracheal anaesthesia. The surgical procedure has previously been described (Heimann, 1962) and therefore is only briefly reviewed here. A Kocher collar incision was used. The infrahyoid muscles were separated and the dissection was continued cautiously, not permitting any bleeding. The inferior thyroid arteries were ligated but not divided. The superior thyroid arteries were ligated twice, but likewise not divided. As a rule the recurrent laryngeal nerve and the parathyroid glands were identified but not freed. In general when a subtotal resection was performed a small remnant of thyroid tissue was left. Thereafter the capsule was sutured with 2/0 chromic catgut. The best possible haemostasis was obtained. The muscles were repaired with chromic catgut and the platysma with interrupted subcutaneous 4/0 plain catgut. The skin was apposed with clips. All ligatures were of chromic catgut except those on the inferior and superior thyroid arteries, which were of black silk. In all cases the excised specimens were sent for pathological examination.

The types of operation performed are related to the diagnosis in *Table I*.

Postoperative management

Drainage of the wound was continued for 24 hours. Removal of every second clip was carried out after 48 hours and the rest after 96 hours. The patient was discharged from hospital on the fourth or fifth postoperative day.

Daily measurements of serum calcium, pulse and temperature were performed. The patient was permitted to drink from the first postoperative day. No postoperative parenteral feeding or fluids were given. The patient was mobilized on the first postoperative day.

Before leaving the hospital the patient was referred for postoperative laryngoscopy. Patients at risk of thyroid deficiency received thyroxine substitution immediately after operation. Patients with toxic adenoma were sent for postoperative thyroid scanning after 3–4 weeks.

Repeat studies of the patient were performed at 1 month (at the time of return to work), 4 months (estimation of protein-bound iodine etc. for euthyroidism), 1 year and thereafter once every year. Patients with complications or other complicating diseases were studied more often. All the patients were continuously followed up in the outpatients' department.

Results

Preoperative complications

Side effects of the anti-thyroid treatment were observed in 42 cases (*Table II*). The incidence of side effects was significantly higher in patients treated with propylthiouracil or methimazole (21–22 per cent) than in the group treated with carbimazole (13 per cent). Most of the side effects were slight and disappeared after reducing the dosage, changing the drug or on complete withdrawal of treatment. No serious side effects (agranulocytosis and/or icterus) were observed in patients treated with carbimazole (*Table III*). The influence of side effects on further preoperative treatment is shown in *Fig*. 3. All the patients could be operated on in a non-toxic phase. In 11 cases the side effects were negligible and did not influence further treatment. In 11 other cases preoperative treatment was continued with iodine. Twenty patients were changed to another anti-thyroid drug. This change was successful in 13 cases while 7 patients showed new or the same complications with the alternative drug. Six of these received iodine and the remaining one was operated on without further preoperative treatment as she was considered to be euthyroid.

Table I: TYPE OF OPERATION PERFORMED RELATED TO DIAGNOSIS

Diagnosis	No. of cases	%	Operation Bilateral	Unilateral
Diffuse toxic goitre	198	73	199	0
Nodular toxic goitre	49	18	32	17
Toxic adenoma	24	9	2	22
Total	271	100	233	39

Table II: SIDE EFFECTS OF PREOPERATIVE DRUG THERAPY

Drug	No. of treatments	Side effects No.	%
Carbimazole	148	20	13
Methimazole	73	16	22
Propylthiouracil	27	6	21

Table III: TYPES OF SIDE EFFECTS OBSERVED

Side effect	Incidence of side effects (%) Carbimazole	Methimazole	Propylthiouracil
Leucopenia	2	0	7
Agranulocytosis	0	2·7	0
Icterus	0	1·3	0
Allergic skin symptoms	7	10	7
Non-specific symptoms	4	8	7

Table IV: INCIDENCE OF PERSISTENT RECURRENT LARYNGEAL PARALYSIS

Type of operation	No. of cases	Paresis No.	%
All operations	272	1	0·4
Reoperation	14	1	7·0
Primary operation	258	0	—

Surgeon not belonging to our thyroid team	20	1	5·0
Primary operation by our thyroid team	236	1	0·4

Table VI: HOSPITALIZATION TIME RELATED TO PREOPERATIVE TREATMENT

Preoperative treatment	Hospitalization time (d)
Anti-thyroid drug + thyroxine	6·5
Anti-thyroid drug + iodine	18
Iodine	32
No preoperative treatment	7

Postoperative complications

There were no operative deaths. There was no case of postoperative thyrotoxic crisis in the patients treated preoperatively with anti-thyroid drugs. One patient developed a postoperative thyrotoxic crisis after incomplete preoperative treatment with iodine.

Recurrent laryngeal nerve paralysis: Our follow-up showed that only 1 patient had a persistent paralysis (*Table IV*). This patient was one of the 14 patients undergoing reoperation. Temporary bilateral paresis was observed in 6 women; 5 of these patients were less than 30 years (7 per cent) and one was over 30 (0·8 per cent). These bilateral transient paralyses disappeared spontaneously, mostly within a week.

Postoperative hypocalcaemia: The total number of patients with permanent hypocalcaemia needing treatment was 6 (2·2 per cent; *Table V*). The incidence in the series of cases with subtotal operation performed by trained thyroid surgeons was 0·4 per cent.

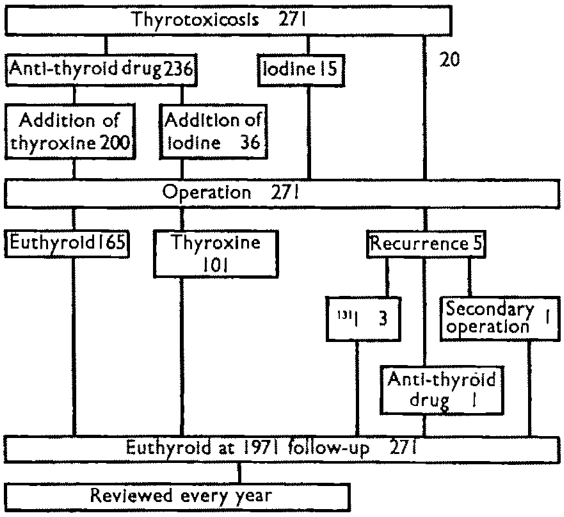

Fig. 4. Summary of the treatment of 271 cases of thyrotoxicosis undergoing surgery.

Hospitalization time

Patients treated preoperatively with an anti-thyroid drug and thyroxine had a similar short hospital stay to the small group of patients with toxic adenoma who received no preoperative treatment. As all treatment with iodine is given to inpatients, the period in hospital for these smaller groups exceeded that of the thyroxine-treated group significantly (*Table VI*).

Late results

Follow-up of the patients for this report was completed in 1971. The observation time was therefore 1–13 years.

Recurrent thyrotoxicosis occurred in 5 cases (2 per cent); 1 underwent reoperation, 3 received radio-iodine and 1 was successfully treated with an anti-thyroid drug. At follow-up in 1971 all 271 patients operated on were euthyroid.

Postoperative hypothyroidism and substitution therapy

The following patients received postoperative substitution from the time of operation: (*a*) cases with strong lymphocytic infiltration; (*b*) cases with a high titre of thyroid antibodies; (*c*) cases with endocrine exophthalmos; (*d*) cases in which an unusually large resection was performed; (*e*) cases undergoing total thyroidectomy; (*f*) cases of malignancy (3 patients). Accordingly 81 patients were given thyroxine substitution (30 per cent).

Among the remaining 190 cases, hypothyroidism was diagnosed and treated in 20 cases (10·5 per cent). A need for postoperative thyroid substitution treatment therefore was found in 38 per cent of the whole series. The incidence was highest in patients with nodular toxic goitre (50 per cent) and lowest in cases with toxic adenoma (8 per cent). The postoperative dosage of L-thyroxine was generally 0·20 mg once a day. No patient received more than 0·20 mg and some were on a lower dosage (0·10 or 0·15 mg).

Other findings

Among the 271 patients operated on for thyrotoxicosis, there were 3 parathyroid adenomas and 9 thyroid tumours of which 4 were malignant. The incidence of parathyroid tumours was 1 per cent and the incidence of thyroid tumours 3 per cent.

Discussion

Many reports of the results of surgical treatment of thyrotoxicosis have been published (Heimann, 1969; Caswell, 1972; Barnes and Gann, 1974; Gillquist, 1974). In this report we want to stress the following important principles:

1. The selection of patients for surgical treatment (*Fig*. 1).
2. Preoperative treatment with anti-thyroid drugs and thyroxine (used in 74 per cent of our series) (*Fig*. 4).
3. The subsequent use of subtotal bilateral resection with ligation of the inferior thyroid artery.
4. The liberal postoperative use of thyroxine in substitution therapy (*Fig*. 4).
5. The treatment of recurrence with methods other than surgery, only 1 patient in our series being operated on twice.

There was no mortality and the surgical morbidity was low. The long term results so far are promising as regards recurrence of the disease (2 per cent). Postoperative treatment with thyroxine is easy to manage and only one investigation per year is necessary. All the patients are reminded to attend for these studies in order to be sure of an adequate follow-up, which is an important part of the treatment.

Treatment with anti-thyroid drugs reduces or abolishes the synthesis of thyroxine and tri-iodothyronine, the level of protein-bound iodine falls and the patient becomes euthyroid. If the treatment continues at a sufficient dosage for full blockage of hormone synthesis the patient becomes hypothyroid and the thyroid gland will be stimulated by an increasing amount of circulating TSH. It is important both for the clinical course of the disease (especially as regards the development of goitre and/or exophthalmos) and for the surgical approach that the patient remains euthyroid and that TSH secretion is continuously inhibited. We therefore give the patients thyroxine (or tri-iodothyronine) as soon as they become euthyroid. At operation the patient is euthyroid and the thyroid gland is empty of thyroxine and tri-iodothyronine. There is no postoperative toxic reaction (rise of pulse or temperature, or nervous symptoms).

The preoperative treatment is sometimes complicated by undesirable side effects of the anti-thyroid drug. Change to another drug or to iodine or in some cases reducing the dosage used nearly always makes it possible to continue treatment and to prepare the patient and the thyroid gland adequately for surgery. In our series carbimazole seemed to be the drug of choice.

Postoperative complications were rare. Thyroid surgery in experienced hands should not carry any postoperative mortality. In this regard the present series is comparable with other larger series (Heimann, 1962). The patients in the latter series (966 cases of thyrotoxicosis treated surgically) were all treated preoperatively with iodine. An important difference between the series treated with iodine and that treated with anti-thyroid drugs and thyroxine is that a postoperative thyrotoxic crisis cannot occur after adequate preoperative treatment with anti-thyroid drugs. There is no excess of thyroid hormones in the completely inhibited gland.

Persistent paralysis of the recurrent laryngeal nerve is a serious complication. It is well known that this complication is frequently seen after difficult reoperations and in radical neck surgery. If thyrotoxic patients are operated on without a constant good view of the operation area the nerve can easily be damaged. Bleeding has to be avoided and the exposure must at all times be adequate. We operate slowly with full control of all bleeding. All vessels, even the smallest, are ligated. In our series of primary subtotal bilateral resections for thyrotoxicosis (258 cases) we had no case of persistent paralysis of the recurrent nerve. An interesting observation in our series concerned 6 female patients with temporary postoperative bilateral paresis of the nerve. In all cases this paresis did not occur immediately after surgery. At extubation there was no bilateral paresis. Symptoms suddenly occurred during the first 24 hours postoperatively. We used to treat such patients by tracheostomy until the paresis disappeared after 5–8 days. Our last cases were treated without tracheostomy. The patients were sedated and the inspired air moistened. They were told that there would soon be a spontaneous regression and complete recovery. The observation of these patients was intensive. It is difficult to explain this temporary paresis. Most of the patients were anxious young women. It is possible that it is a toxic effect (lidocaine adrenaline used for subcutaneous infiltration?, anaesthetic drug?, preoperative treatment?); one also has to ask if it is a real paresis or perhaps a traumatic damage of the vocal cords? Intubation and the maximal dorsiflexion of the neck during surgery could be responsible. Respiratory difficulties begin during the first hours after extubation and disappear completely as suddenly. It therefore seems to be a local affection probably caused by several factors.

Postoperative hypocalcaemia is the most severe complication, for it is necessary to give these patients lifelong treatment with approximately four blood studies a year. The risk is greatest in connection with reoperation. In our series hypoparathyroidism was observed in 3 of 14 (21 per cent) reoperations. Reoperation should therefore be avoided, which means adequate and complete primary operations and nonsurgical treatment of recurrences.

Of the 6 cases with hypocalcaemia, 3 occurred after primary surgery, one in connection with one of our two total thyroidectomies for thyrotoxicosis and one among the small group of 20 patients who were not operated on by members of our thyroid team. In 236 primary subtotal thyroidectomies for thyrotoxicosis performed by trained thyroid surgeons only 1 patient developed postoperative hypoparathyroidism; an incidence of 0·4 per cent.

Thus, primary subtotal thyroidectomy for thyrotoxicosis after preoperative treatment with antithyroid drugs and thyroxine and performed by experienced surgeons has no mortality and a very low postoperative morbidity. Surgery therefore offers an effective treatment of thyrotoxicosis. The long term results are good. Our aim is to avoid recurrence of thyrotoxicosis, for it represents such a difficult therapeutic problem. In order to detect hypothyroidism and recurrent goitre all our patients are under continuous observation and review after operation. Cases in which the risk of hypothyroidism is greater receive prophylactic treatment with thyroid hormone. With our programme of therapy of thyrotoxicosis we can offer the patient treatment which in all cases leads to euthyroidism. Most patients are cured by preoperative treatment and surgery, approximately every third patient also needs postoperative substitution and a very few need additional treatment with radio-iodine or antithyroid drugs; all have to be followed up (*Fig.* 4).

An important point in this programme is the fact that the treatment brings the patient to a steady euthyroid state more quickly than radio-iodine treatment or medical treatment. Preoperative treatment can be given on an outpatient basis in most cases. The majority of patients can also work from the time when they become euthyroid until the day before operation. Hospitalization time is minimal (6–7 days), and postoperatively most patients are back at work after 4 weeks.

An observation worth mentioning is the detection at operation of thyroid and parathyroid tumours. Thyroid carcinoma can be associated with thyrotoxicosis and is often undetected by diagnostic measures such as scanning or aspiration needle biopsy. We found such tumours in 4 per cent of our series as a consequence of our surgical technique with full dissection of arteries, nerve, parathyroids, especially the dorsal aspect of the thyroid gland and the paratracheal thyrothymic fascia.

Conclusions

Preoperative preparation with anti-thyroid drugs in combination with thyroxine or tri-iodothyronine allows safe surgical treatment of thyrotoxicosis. This corresponds with structural and ultrastructural results and pathophysiological findings. We would recommend the following programme:

1. Surgical treatment should be chosen for young patients (20–50 years) with diffuse toxic goitre or toxic adenoma and for older patients in whom nodular goitre is producing mechanical symptoms.

2. Preoperative treatment should be instituted and continued with an anti-thyroid drug until the patient is completely euthyroid, followed by a maintenance dosage of the drug sufficient to block all thyroid hormone synthesis. In addition, the patient should receive substitution thyroxine (0·20 mg daily) or tri-iodothyronine (0·020 mg four times daily). Thyroid

hormone should be given for at least 4 weeks preoperatively, most of our patients receiving this treatment for 2–4 months.

3. Surgery should be performed by surgeons with special experience of this work. Bleeding has to be avoided. All important structures such as vessels, nerves and the parathyroids must be identified. Both the superior and inferior thyroid arteries should be ligated. The aim of the resection should be to avoid recurrence of the thyrotoxic symptoms.

4. The care of the patients should include pre- and postoperative laryngoscopy and daily serum calcium estimation. Patients who are considered to carry a larger risk of hypothyroidism should receive prophylactic thyroxine treatment postoperatively. All patients should be followed up, probably for the rest of their lives.

5. Recurrence of thyrotoxicosis should be treated by methods other than surgery.

With this programme we can offer the patient a safe, quick and effective way to euthyroidism. Preoperative treatment with anti-thyroid drugs and thyroid hormones has real advantages and should be adopted as the method of choice.

Carcinoma arising in thyroglossal duct remnant: case reports and review of the literature

PRAKASH C. SAHARIA*

SUMMARY

Two cases of thyroglossal duct cyst carcinoma are presented and the world literature is reviewed. There are only 74 cases reported to date. In nearly all the cases the clinical diagnosis was thyroglossal cyst. Although the great majority of the tumours were papillary adenocarcinomas, 13·15 per cent were of other histological types. The treatment has been quite variable, but the most common initial treatment was Sistrunk's (1928) operation. Following the establishment of the diagnosis of malignancy, thyroidectomy was done in several cases, but it failed to show any evidence of malignancy in most of the thyroids removed, which establishes firmly the de novo origin of these tumours from the thyroglossal duct remnant. In only one case had tumour disseminated to distant organs, the lung, liver, etc. The scepticism as to whether some of the carcinomas associated with thyroglossal duct remnants may not in fact represent metastases from a small primary tumour of thyroid gland is examined. It appears that, though a possibility of primary or metastatic tumour in the thyroid does exist, the probability does not appear to be high. From our own experience it is suggested that local excision followed by radiotherapy, irrespective of recurrence, may be worth considering for the treatment of such carcinomas.

CARCINOMA arising in a thyroglossal duct remnant is rare. Only 74 cases have been reported in the world literature to date. Most have been papillary adenocarcinomas, but squamous cell lesions have also been documented. The present report adds 2 cases to the literature and documents common clinical data for this group of unusual tumours.

Case reports

Case 1: An 81-year-old white female was admitted to Derby City Hospital (Eng.) in February 1971 with a mass in her neck of 4½ months' duration. It was painless but increasing in size rapidly. There were no related symptoms. Physical examination revealed a 4 × 5-cm mass at the level of the thyroid cartilage, slightly to the left of the midline. It was smooth, spherical in shape and firm in consistency. It was adherent to the hyoid bone, but was not attached to the overlying skin. The mass moved with swallowing and protrusion of the tongue. There were no palpable cervical lymph nodes, and the thyroid gland felt normal in size and consistency. X-ray of the chest showed no abnormality.

Excision of the mass, including the left hyoid bone, strap muscles and part of the thyroid cartilage and thyroglossal duct up to the foramen caecum, was carried out *en bloc* through a collar incision. The thyroid gland was exposed and was found to be normal. Exploration of the neck for enlarged cervical glands was negative.

Examination of the specimen revealed a cyst, 6 cm in diameter, containing a nodule in the wall. The wall of the cyst was lined by squamous cell epithelium and the nodule itself was a well-differentiated squamous cell carcinoma invading the surrounding tissue and strap muscles.

The postoperative course was uneventful and the patient has remained free of any evidence of recurrence for 3 years following surgery.

Case 2: A 54-year-old white male was admitted to Wordsley Hospital, Worcester, in August 1970 with a neck mass of 3 months' duration.

Physical examination revealed a smooth, cystic, spherical, non-tender, 5 × 4-cm mass overlying the left thyroid cartilage. The mass moved with swallowing and protrusion of the tongue. The thyroid gland felt normal in size and consistency. There were no enlarged cervical lymph nodes.

The mass was removed through a collar incision along with the adherent strap muscles, left hyoid bone, part of the thyroid cartilage and the thyroglossal duct *en bloc*. The thyroid gland was exposed and was found to be normal. No enlarged cervical glands were detected.

Examination of the specimen revealed a cyst 5 × 4 × 2 cm with a thick fibrous wall and an irregular fibrotic plaque in the wall of the cyst. Microscopically, the wall was fibrotic with foci of active and chronic inflammation. In parts of the cyst, groups of papillary elements were found which consisted of orderly, well-differentiated neoplastic cells consistent with papillary adenocarcinoma. Some follicular neoplastic elements containing colloid were also present. Tumour cells were observed in the overlying strap muscles (*Fig.* 1).

The patient's postoperative recovery was uneventful. In view of the muscle invasion, the possibility of incomplete excision and the fact that the patient was a poor surgical risk, a course of radiotherapy was given.

There is no evidence of recurrence after 3½ years' follow-up.

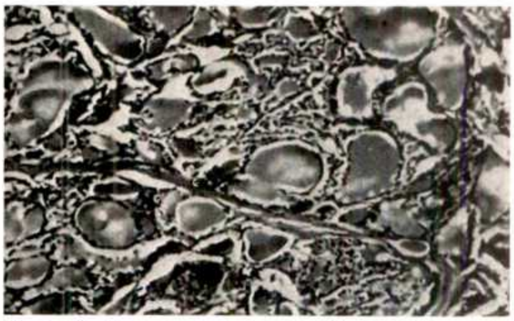

Fig. 1. Papillary adenocarcinoma with follicular neoplastic elements containing colloid. (× 180.)

Discussion

The thyroid gland forms at about the fourth week of embryonic life from a median diverticulum of the ventral pharyngeal wall at a position marked in adult life by the foramen caecum. As the thyroid gland migrates downwards, it forms a duct behind it in its path. The duct can be lined by squamous, columnar or transitional epithelium. Ordinarily the duct disappears at the sixth or seventh week of fetal life.

Incomplete obliteration, however, may lead to the development of a thyroglossal duct cyst which can appear in the midline anywhere between the foramen caecum and the suprasternal notch. In addition, thyroid rests can appear along this tract.

A survey of literature reveals 74 cases, and with the addition of the present 2 cases a total of 76 cases becomes available for analysis.

Clinically, the presenting symptom has generally been a gradually increasing cervical mass with variable location (*Table I*), in some cases associated with hoarseness and dysphagia. The known duration of the mass prior to surgery ranges from 10 days to 15 years. In the majority of cases the thyroid gland was reported to be normal on clinical and gross examination. Only 2 out of the 76 cases were associated with carcinoma of the isthmus and the right lobe of the thyroid (Rees and Brown, 1953; Mobini et al., 1974).

The pathological diagnoses were papillary adenocarcinoma in 66 cases, adenocarcinoma in 2, squamous cell carcinoma in 5 and mixed follicular and papillary carcinoma in 3 (*Table II*). The case reported by Dalgaard and Wetteland (1956) appears to have been a solid undifferentiated carcinoma and bears resemblance to the recently recognized medullary carcinoma with amyloid stroma.

Judd (1963) has stated that thyroid tissue in and around the thyroglossal duct is rarely encountered and that the occasional recording of papillary carcinoma of a thyroglossal cyst or sinus is erroneous. He contends that when a papillary carcinoma is encountered in this region the thyroid gland is always the source, and that if these were true carcinomas of thyroglossal duct or sinus origin they would be expected to be of the squamous cell type. Thyroid tissue has been found with thyroglossal duct remnants by others, however, in incidences ranging from 3 to 36·5 per cent (Ward et al., 1949; Choy et al., 1964). In addition, 4 cases of squamous cell carcinoma (Owen and Inglesby, 1927; Nachlas, 1950; Shepard and Rosenfeld, 1968; Mobini et al., 1974) arising from the thyroglossal duct have been reported. Furthermore, it is certainly possible that the stomodeal epithelium of the thyroglossal duct with its embryological potential of thyroidogenesis could produce a neoplasm resembling that of thyroid origin.

There is no unanimity of opinion regarding the surgical approach to such tumours. In most cases Sistrunk's (1928) operation was carried out. Following histological diagnosis of malignancy, further treatment has included re-excision of local tissues, bilateral block neck dissection, thyroid administration and radioiodine therapy (Zamrazil et al., 1971). Although thyroglossal duct cyst presents as a swelling slightly lateral to the midline, developmentally the thyroglossal duct cyst is a midline structure. Malignancy arising within it, therefore, can metastasize to lymph nodes on either side of the neck. Unilateral dissection has no place in the prophylaxis of spread, since it is impossible to predict which side (if either) will be the site of further metastasis. The follow-up of the reported cases ranges from 3 months to 28 years. Only 13 cases of recurrence have been reported. Twenty-nine cases have been followed up for more than 5 years (*Table III*). In only 1 case (Maxwell and Marchetta, 1960) were there distant metastases. The remaining instances were local recurrences treated by repeated local excisions or block dissection.

Because of the paucity of cases the long term prognosis is not clearly known. However, there is no reason to believe that this tumour should have different biological behaviour from carcinoma of the thyroid gland.

Acknowledgements

I would like to thank Mr A. W. Anderson, Consultant, City Hospital, Derby, and Mr M. Hershman, Consultant, Wordsley Hospital, near Stourbridge, for permitting me to publish their cases. I am also grateful to Dr John L. Cameron, Associate Professor of Surgery at the Johns Hopkins Hospital, Baltimore, for his help and guidance in preparing this manuscript.

Secondary carcinoma of the thyroid gland

JOHN A. THOMSON, J. S. KENNEDY, M. K. BROWNE AND J. HUTCHISON*

SUMMARY

Two patients are described who presented with clinically solitary thyroid nodules which were found to be due to metastatic disease from the kidney and colon respectively. Removal of the solitary metastatis in one patient resulted in disease-free survival for over 5 years.

THERE has been considerable interest for some years in the clinically solitary thyroid nodule and the possibility of it being the site of a thyroid tumour. The likelihood of the thyroid being the site of a solitary metastasis has been much less commonly reported. The purpose of this communication is to document 2 such cases.

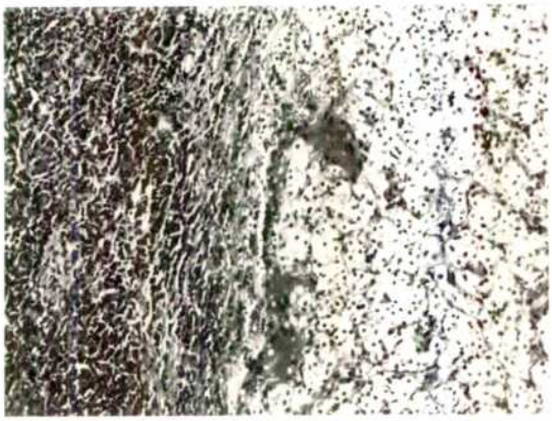

Fig. 1. *Case* 1. Secondary clear cell carcinoma of the kidney in the thyroid which shows chronic thyroiditis of Hashimoto type. HE. (×112.)

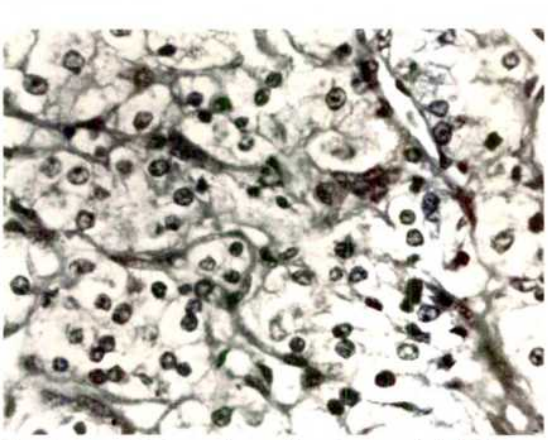

Fig. 2. *Case* 1. Primary clear cell carcinoma of the kidney. HE. (×450.)

Case reports

Case 1: A. O., a female aged 74 years, had a past history of carcinoma of the uterine cervix which had been treated by hysterectomy at the age of 58 years; there had been no subsequent symptomatology.

The patient presented to Glasgow Royal Infirmary when aged 63 because of left renal colic and haematuria. Investigation showed a non-functioning left kidney, and a left nephrectomy was performed in October 1963. A clear cell carcinoma of the kidney with no evidence of vascular invasion was found and there was no evidence of metastatic disease of the liver or the peritoneum at the time of operation.

In 1964 she was first noted to have a nodule in the region of the thyroid gland, but this was asymptomatic and was not further investigated. In 1969 she was referred back by her general practitioner because of enlargement of the thyroid nodule and the onset of some pressure symptoms. At that time she was clinically euthyroid and a cystic nodule of the right lobe of the thyroid displacing the trachea to the left was noted on examination. Thyroidectomy was performed in October 1969 and, as shown in *Fig.* 1, the appearance of the resected thyroid showed the presence of metastatic tumour of clear cell type in a gland showing thyroiditis of Hashimoto type. For comparison *Fig.* 2 shows the primary clear cell carcinoma of kidney removed in 1963. Following the operation the patient was treated by thyroxine therapy and has remained alive and well without any signs of recurrence of tumour.

Case 2: M. S., a female aged 44 years, presented in 1967 to Glasgow Royal Infirmary with a history of exertional dyspnoea and effort angina. She also complained of menorrhagia. A hypochromic anaemia of 7 g was diagnosed and she was treated with oral iron with improvement but relapsed the following year when she had a hypochromic anaemia of 5·4 g. A barium meal examination was negative and she was again treated with oral iron. In 1969 she was re-investigated because of recurrent anaemia, and at that time a vague mass was palpable in the right side of the abdomen. Barium meal and enema studies and intravenous pyelography were all normal, but at laparotomy she was found to have a carcinoma of the hepatic flexure of colon. This was treated by a right hemicolectomy. At operation there was no obvious metastatic disease but there was local invasion at the site of operation.

In September 1973 the patient was referred to the Thyroid Clinic at Glasgow Royal Infirmary with 4-month history of a thyroid nodule. She was euthyroid and on examination had a clinically solitary nodule of the isthmus of the thyroid gland. This was hard in consistency and was thought on clinical grounds to be malignant. There were no clinical features of metastatic disease but chest X-ray showed a small shadow in the left lung field. Tests of thyroid function were in the euthyroid range. The thyroid nodule was cold on scanning with radioactive iodine.

A preoperative diagnosis of thyroid malignancy was therefore made, and in view of the history of previous bowel surgery the possibility of this being metastatic was strongly considered. It was decided to explore the neck as this might show metastatic tumour, thus confirming the initial diagnosis; alternatively a primary thyroid carcinoma requiring treatment in its own right might be found. Accordingly, the neck was explored in October 1973 and the nodule of the isthmus removed. As shown in *Fig.* 3, this was found to be secondary tumour,

invading the thyroid gland; the nature of the tumour was compatible with a colonic primary. For comparison a section of the original tumour is shown in *Fig.* 4.

Following thyroidectomy the patient was given a 5-day infusion of flurouracil. She remained well until March 1974 when she developed signs of cerebellar disease. Surgical exploration revealed secondary tumour in the cerebellum and hydrocephalus. Following resection of the metastatic tumour she improved temporarily but died 1 month later.

Discussion

Although secondary carcinoma of the thyroid gland has been recognized to occur as an infrequent finding it has been relatively disregarded even in major texts devoted to the thyroid. One of the few books on thyroid diseases which mentions the condition is that of Means et al. (1963), who amongst their list of recognized primary sources of tumour to metastasize to the thyroid include the two documented here, namely the kidney and the intestine. Recently, Gault et al. (1974) have recorded an example of clear cell renal carcinoma masquerading as thyroid enlargement, in this instance as a multinodular goitre, and reviewed the literature.

Metastatic tumours of the thyroid gland are of course seen in patients with very disseminated neoplasia, especially those from breast or bronchial carcinoma or from malignant melanoma. It should be emphasized, however, that in both the cases reported here the patient presented with a clinically solitary thyroid nodule in an otherwise fit patient, and it is worth while bearing in mind the possibility of metastatic thyroid disease in any patient who has had previous surgery for a malignant tumour and who subsequently presents with a solitary thyroid nodule. The experience of the first case led to the correct preoperative diagnosis being made in the second. The clinical course in *Case* 1 shows the value of resecting such an accessible solitary metastasis.

The significance of occult skeletal metastases, detected by skeletal scintigraphy, in patients with otherwise apparently 'early' mammary carcinoma*

C. S. B. GALASKO†

SUMMARY

Fifty patients with apparently 'early' mammary carcinoma on clinical, radiological and biochemical grounds had a skeletal scintigram carried out when they first presented. Twelve (24 per cent) of the patients had a positive scintigram. All these patients have developed metastatic disease in the first 5 years following mastectomy, and at least 9 (75 per cent), and probably 10 (83 per cent), have died from mammary carcinoma during this period. This compares with 10 (26 per cent) of the patients with a negative scintigram who have developed recurrent or metastatic disease, of whom 8 (21 per cent) have died from their disease. Five years following mastectomy none of the patients with a positive scintigram was alive and free from disease, compared with 25 (66 per cent) of the patients with a negative scintigram.

It would appear that skeletal scintigraphy is the most sensitive method of detecting skeletal metastases and of staging breast carcinoma at the moment. Where practicable, this investigation should be carried out before embarking upon treatment for any particular patient, and this certainly should become part of any clinical trial comparing different therapeutic regimens. However, before some of the newer bone-seeking isotopes are used in this way, further studies are required to determine their false positive rate.

It is now well established that skeletal scintigraphy is more accurate and sensitive than conventional methods for the early detection of skeletal metastases (Galasko, 1972). It has also been shown that occult skeletal metastases are present on the scintigram in approximately 25 per cent of patients with apparently 'early' mammary carcinoma (Galasko, 1972). These studies did not show the significance of these occult lesions, or whether they affect the survival of the patients. An attempt to answer this question has been made by carefully following up 50 consecutive patients with apparently 'early' mammary carcinoma who had had a skeletal scintigram when they first presented.

Patients and methods

Fifty women with apparently 'early' mammary carcinoma were studied. Each patient had a careful clinical examination, a radiographic skeletal survey, an X-ray of her chest and biochemical liver function tests when she first presented. In addition, each patient had a skeletal scintigram. The method of scintigraphy has previously been reported (Galasko, 1969); ^{18}F and a gamma camera were used, and the scintigram was looked at in conjunction with the X-rays. All the investigations were carried out before treatment for the mammary carcinoma was instituted. All the patients had a mastectomy, either simple or radical, followed by a course of radiotherapy to the local lymph nodes. The patients have all been followed up for 5 years.

The results of the scintigram were ignored in determining treatment for the patients. If a patient developed other evidence of dissemination of her cancer, appropriate treatment was instituted.

Table I: OUTCOME IN 50 PATIENTS WITH APPARENTLY 'EARLY' MAMMARY CARCINOMA

	Scintigram positive		Scintigram negative		Total	
	No.	%	No.	%	No.	%
Number of patients	12	24	38	76	50	100
Subsequently developed disseminated cancer	12	100	10	26	22	44
Died from cancer	9 ?10	75 83*	8	21	17 ?18	34 36*
Died from intercurrent disease	0		3	8	3	6
Alive at 5 years	2	17	27	71	29	58
Alive with disseminated disease	2	17	2	5	4	8
Alive with no evidence of recurrence	0		25	66	25	50

* *See* text.

Results

In every patient the local tumour was thought to be operable. On the TNM classification it was T1 or T2, and in 2 patients with large breasts T3, by size. There was no fixity. The lymph nodes were either N0 or N1. Clinically, there was no evidence of dissemination of the disease. The radiographic skeletal survey, X-ray of the chest and liver function tests were entirely normal.

In 12 patients (24 per cent) lesions were found on the scintigram. In the remaining 38 (76 per cent) the scintigram was entirely normal (*Table I*). During the 5-year period all the patients with a positive scintigram developed metastatic disease, not only confirming the scintigraphic findings but usually involving other organs as well. During the same period 10 (26 per cent) of the patients with a negative scintigram developed either local recurrence or distant dissemination of their tumour.

---

* Based on a paper presented to the Surgical Research Society in July 1974.

† Department of Surgery, Royal Postgraduate Medical School, London.

Nine (75 per cent) of the patients with a positive scintigram have died from mammary carcinoma during the first 5 years. The tenth patient was lost to follow-up. Eighteen months following mastectomy, when she was desperately ill with hepatic and pulmonary metastases as well as skeletal metastases, she decided to return to Jamaica to die. If she is included in the deaths from mammary carcinoma the figure is 10 (83 per cent). This compares with 8 (21 per cent) of the patients with a negative scintigram who have died from mammary carcinoma during this period (*Table I*). None of the patients with a positive scintigram died from intercurrent disease. There were 3 such deaths (8 per cent) in the negative scintigram group. At autopsy in these patients there was no evidence of residual or metastatic tumour.

Two (17 per cent) of the patients with a positive scintigram were alive at 5 years but both had advanced mammary carcinoma. There were no patients in the positive scintigram group who were alive without evidence of recurrence at 5 years. In the negative scintigram group 27 (71 per cent) were alive at 5 years, 2 (5 per cent) of whom had metastatic disease. In this group 25 (66 per cent) patients were alive without evidence of recurrence at 5 years (*Table I*).

Discussion

The results of this study indicate that occult skeletal metastases detected by skeletal scintigraphy are significant and affect the patient's prognosis. There were no patients with a positive scintigram who were alive and free from disseminated disease at 5 years, compared with 66 per cent of patients with a negative scintigram. Twenty-six per cent of the patients with a negative scintigram developed metastatic disease and many of these developed skeletal metastases as well. These lesions were not detected by skeletal scintigraphy.

The results of the study also indicate that conventional methods of staging mammary carcinoma are grossly inaccurate. Using skeletal scintigraphy, approximately one-quarter of patients with otherwise apparently 'early' mammary carcinoma have occult skeletal metastases which severely affect their prognosis. Unfortunately, pulmonary and hepatic scintigraphy is not as accurate. Obviously the ideal would be some method of detecting tumour at all sites, be it primary or secondary, but until such a method becomes available, skeletal scintigraphy would appear to be the method of choice for staging mammary carcinoma, particularly in patients who are being admitted to a controlled clinical trial comparing different therapeutic regimens. Estimation of the carcino-embryonic antigen, α-feto protein, and other methods currently available are not sufficiently reliable for accurately staging apparently 'early' disease, although they may be very useful for assessing progress (Galasko, 1974)

In the present study there were no false positives on the skeletal scintigram. A localized increased concentration of bone-seeking isotopes is not specific for metastatic disease, and any condition which is associated with new bone production will show up as an area of increased concentration of the isotope (Galasko, 1973). Benign lesions, for example, Paget's disease of bone, osteo-arthritis, osteomyelitis with subperiosteal bone formation, fracture, etc., will be seen on the X-ray, as will primary malignant bone tumours. In this study a lesion was only reported if the X-ray was normal and there was no possible benign cause for the localized increased uptake of isotope. Where a benign lesion, which may be responsible for the uptake of isotope, was seen on the X-ray that particular area was regarded as normal for that patient. Using this method there were no false positives.

In recent years $^{99}Tc^{m}$-tagged pyrophosphate, polyphosphate and diphosphonate have become available for bone scanning. The technetium-tagged diphosphonate would appear to be the most suitable of these isotopes (Lavender, 1974; Tofe and Francis, 1974). ^{18}F is only available from the cyclotron or linear reactor and because of its short half life of 1·8 hours can only be used in fairly close proximity to the site of production. Technetium is much more readily available. Comparative studies between ^{18}F and $^{99}Tc^{m}$ diphosphonate indicate that the latter is probably more sensitive than the ^{18}F and may detect more and smaller metastases (Silberstein et al., 1973; Lavender, 1974). Because $^{99}Tc^{m}$ diphosphonate is so sensitive, very minor benign changes may show up as areas of localized increased uptake when no changes are seen on X-ray, and several false positives have been reported with technetium diphosphonate (Lavender, 1974). Before it comes into routine use for skeletal scintigraphy, and particularly for the staging of apparently 'early' mammary carcinoma, further studies are necessary to determine the false positive rate.

The results of this study also suggest that there may be three stages of mammary carcinoma: *early mammary carcinoma*, where there is no clinical, radiographic or scintigraphic evidence of dissemination of the disease, *early advanced disease*, where occult skeletal metastases are seen on the scintigram but there is no clinical or radiographic evidence of dissemination of the disease, and *advanced disease*, where metastases are obvious on clinical or radiographic examination. Clinical trials should compare separately patients in each subgroup. If patients with early advanced disease are excluded from clinical trials comparing different forms of local therapy, a significant difference may emerge between different forms of treatment.

The very interesting group would appear to be the patients with occult skeletal metastases. There is evidence which suggests that chemotherapy is most effective when the tumour deposits are still very small (Rowe-Jones, 1969). It is possible, therefore, that these patients should be treated by some form of adjuvant therapy as well as local excision of the primary tumour when they first present. Whether such adjuvant therapy will improve what is otherwise a very poor prognosis remains to be determined and could well be the subject of several controlled clinical trials.

ETHICON
TRADEMARK
Eyeless needled sutures

REDUCE TRAUMA

ETHICON* Eyeless Needled Sutures offer three outstanding advantages over traditional eyed needles.

Point 1 Reduced trauma–with ETHICON eyeless needles there is no large eye and only one strand of material to pass through tissue.

Point 2 Consistent high quality–by precisely controlled manufacture of a complete sterile suture in a single package.

Point 3 A new sharp needle every time.

The choice is yours

Most surgeons agree that there is no universal suture. Most probably there never will be. Each patient, each procedure, and each layer of tissue differs from the next. This is why we at ETHICON manufacture such a comprehensive range of eyeless needled sutures.

You can choose from our wide selection of materials, absorbable and non-absorbable, securely attached to a stainless steel needle of your choice. The consistent high quality of ETHICON eyeless needled sutures provides predictable performance. This enables you to concentrate on the most critical aspect of your surgery–the well-being of the patient.

Acute cholecystitis

P. A. M. RAINE AND A. A. GUNN*

SUMMARY

One hundred and fifty-six successive patients have been admitted with the clinical diagnosis of acute cholecystitis and have been treated by operation on the next operating list. The diagnosis was correct in 154 and a diagnostic pathway has been determined. The clinical features, investigations, bacteriology and pathology are discussed.

There is an increased need for choledochotomy in acute cholecystitis and this bile is more commonly infected than in the elective patient. It is suggested that those with infection can be identified prior to operation and should be treated with antibiotics on admission.

The morbidity of operation on patients with uninfected bile is no greater than in those receiving elective surgery, and operative treatment is recommended for both groups of patients.

THE management of acute cholecystitis remains controversial. The proponents of conservative treatment record the difficulty in confirming the diagnosis, with an error rate of between 5 and 24 per cent (Essenhigh, 1966; Van der Linden and Sunzel, 1970). Emergency surgery is said to carry a higher risk, with spread of infection and increased technical difficulty, particularly in detecting stones in the common bile duct (Wenkert et al., 1969; Jersky, 1970). Surgical treatment is advocated to abolish symptoms by removing the source of infection, to avoid further attacks and to allow the patient to return to normal life at an early date (Sokhi and Longland, 1973). This form of treatment reduces the time spent in hospital and expedites return to work with decreased insurance claims (Payne, 1969).

A consecutive series of patients has received operative treatment on the next operating list, and the clinical, operative, bacteriological and pathological data were recorded in a prospective manner.

Patients

Between 1965 and 1973, 156 patients were admitted to one surgical unit with the clinical diagnosis of acute cholecystitis. Attempts were made to confirm the diagnosis and to correct any abnormalities in the general health of the patient before the operation. During the same period 421 patients were admitted from the waiting list for elective biliary surgery and formed a basis for comparison.

Clinical details (*Table I*)

The emergency group of patients showed an increase in the ratio of male to female patients and the mean age was greater despite the shorter duration of symptoms. The increased frequency of a history of jaundice and abnormal liver function tests indicated that the pathological process was more advanced.

The diagnosis was correct with two exceptions. Both of these patients had pain, jaundice and a leucocytosis; the first had a duodenal perforation with marked oedema of the lesser omentum, and the second was proved to have haemorrhage into an infected hepatic metastasis.

Abdominal X-rays showed stones in 25, a calcified gallbladder in 4, a soft tissue swelling in 4 and gas in the biliary tract in 9 patients. No abnormality diagnostic of biliary tract disease was seen in the remaining 131, although a number of films showed other signs indicative of pathology in the right hypochondrium.

Table I: CLINICAL FEATURES OF THE EMERGENCY AND ELECTIVE GROUPS

	Emergency	Elective
Sex ratio (female : male)	3 : 2	3 : 1
Mean age (yr)	57·6	55·2
Duration of symptoms (%)		
<1 yr	52·0	13·7
>5 yr	19·0	40·8
History of jaundice (%)	36·4	23·5
Abnormal liver function (%)	49·3	20·0
Positive straight X-ray (%)	27·3	16·0

Oral cholecystography is only of value in patients who are neither vomiting nor have become jaundiced; 87 patients had this investigation and in 70 contrast was not concentrated in the gallbladder. When there is no vomiting, pyloric stenosis, diarrhoea, malabsorption and impaired liver function, absence of opacification was interpreted as evidence of obstruction of the cystic duct.

Intravenous cholangiography is limited to patients with normal liver function and by difficulties of interpretation when the ducts are poorly opacified. Twenty-four patients had this examination; 15 showed a normal duct system without filling of the gallbladder, 6 had stones in the common duct and 3 had a dilated duct.

Liver function tests were abnormal in 75 patients which suggested an element of obstruction in the common bile duct and placed a limit on the use of diagnostic X-rays. The bilirubin was raised in 64 cases, the alkaline phosphatase in 41, SGPT in 19 and prothrombin ratio in 24 patients.

Operative treatment (*Table II*)

All the operations were performed within 5 days of admission and the duration of symptoms before admission varied from less than 24 hours to 9 days. Thirty-one per cent of the patients required choledochotomy compared with 12 per cent in the elective series. Operative cholangiography has proved to be effective in the emergency situation (*Table III*), although 13 patients did not have this investigation: 7 because they were admitted early in the series before the technique was routine, 3 for technical reasons and 1 patient was iodine sensitive. In 2 patients the stones were felt and the duct opened without prior cholangiography.

Subphrenic abscess	1·9	1·4
Waltman Walter's syndrome	1·3	0·2
Bacteriogenic shock	2·6	0·2
Oliguria	1·3	0·7
Death	2·5	0·2

Results given as percentages.

It proved difficult to record in detail the technical problems encountered, but the degree of difficulty was indicated and was found to increase progressively after 7 days from the onset of symptoms.

Pathological and bacteriological findings

The pathologist reported acute cholecystitis in 9·3 per cent, acute and chronic cholecystitis in 67·4 per cent and chronic cholecystitis in 23·3 per cent. Although this appears paradoxical, patients presenting with acute right hypochondrial pain may have obstruction in the biliary tract with or without inflammation.

In these three groups of patients there was no difference in sex, age or duration of symptoms, but half of the patients with chronic cholecystitis had a history of jaundice compared with less than a third of the other patients. The proportion of patients undergoing oral cholecystography was similar in each group but half of those with chronic disease had a functioning gallbladder compared with 1 in 10 of the remainder.

Thirty-five per cent of the immediate surgery patients had positive culture results of the bile, gallbladder or stones compared with 19 per cent in the elective series. Positive culture was more frequent in the patients with acute or acute with chronic pathological changes.

An attempt was made to correlate the pathological findings with the presence of a pyrexia or leucocytosis but this proved of little value (*Table IV*).

Postoperative complications (*Table V*)

Postoperative complications were recorded prospectively and, in particular, an X-ray was taken of the chest on the third postoperative day. Fifty-eight per cent of the patients in the emergency and elective groups had at least one complication, but when the 'postoperative chest' was excluded the incidence was 19·5 per cent in the emergency group and 16 per cent in the elective group. However, the finding of a positive culture of the bile increased the incidence to over 30 per cent in both groups of patients.

The complications that were more frequent in the emergency patients were those associated with infection and leakage of bile. The mortality was 2·5 per cent in this series compared with 0·2 per cent in the elective operations in the same period. The 4 deaths were in patients aged over 60 years with symptoms for more than 6 days. Each patient had infected bile but the

Table VI: DETAILS OF THE PATIENTS WHO DIED IN THE EMERGENCY GROUP

Sex	Age	Duration of symptoms (d)	Pathology	Operation	Post-mortem findings
F	61	9	Acute cholecystitis	Cholecystectomy	Coronary atheroma, pyelonephritis, pulmonary congestion
F	68	6	Perforated empyema	Cholecystectomy, choledochotomy	Pulmonary emboli

F	60	6	Acute cholecystitis	Cholecystectomy, choledochotomy	Fatty infiltration of the heart

post-mortem failed to confirm this as the cause of death (*Table VI*).

Discussion

Diagnosis

There was no formal scheme for the diagnosis of acute cholecystitis and two errors were made. However, a diagnostic pathway can be determined from the information obtained and appears to be helpful in confirming the clinical suspicion of acute biliary tract disorder if not of histological acute cholecystitis (*Fig.* 1).

Straight X-rays reveal the presence of biliary disease in 25 per cent but do not exclude other causes of pain such as acute pancreatitis. In the remainder jaundice suggests biliary tract disease and the liver function tests identify its obstructive nature. The presence of abnormal liver function tests limits the use of oral and intravenous cholangiography, and in such patients percutaneous transhepatic cholangiography is potentially dangerous. Retrograde cholangiography could have a place where the cause of the jaundice is in doubt, but in the majority laparotomy is essential and operative cholangiography permits accurate evaluation.

If the straight X-rays are negative and the patient is not jaundiced, cholecystography by the oral route is possible unless the patient is vomiting, when intravenous cholangiography is preferred. The oral cholecystogram may fail to reveal any filling of the gallbladder, and an intravenous cholangiogram would be necessary if there was reasonable doubt of the diagnosis.

In this series 15 patients without jaundice and with a negative straight X-ray had no further investigation and the decision to operate for acute cholecystitis was made on clinical grounds alone. A further 23 patients with a non-functioning gallbladder were treated by operation without an intravenous cholangiogram as suggested above.

Clinical judgement varies and it is suggested that the diagnostic pathway should be followed to provide further evidence of acute cholecystitis.

Infection

Various studies have suggested that infection is important in the mortality and morbidity of biliary operations (Haw and Gunn, 1973; Keighly and Graham, 1973). Infection in the bile was more common in the emergency series, as was the need for choledochotomy, and these facts may explain the higher mortality. However, where infection was not proved the morbidity and mortality were the same in both groups.

Certain criteria have been shown to be associated with an increased incidence of positive bile culture (Haw and Gunn, 1973), and if the diagnosis can be made the patient should receive appropriate antibiotic therapy prior to having the source of the infection removed. An analogy can be drawn with the treatment of acute appendicitis.

In the other patients where infection is considered unlikely there is no evidence of increased morbidity following operation, which is straightforward. If competent surgeons are available it is suggested that these patients should be treated by operation; but, if so decided, they could be treated conservatively with close observation.

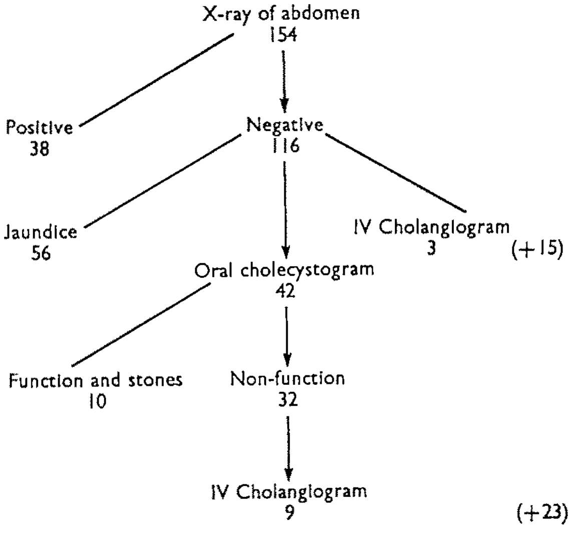

Fig. 1. The diagnostic pathway in the present series.

Conclusions

1. A diagnosis of cholecystitis can be reached in nearly every patient admitted as an emergency with 'acute cholecystitis', although in 25 per cent the pathology is chronic cholecystitis with no evidence of acute inflammation.
2. The operative mortality in patients with 'acute' cholecystitis is higher than in elective operations, but the former is a different group of patients with a higher incidence of infection and of stones in the common duct.
3. It is argued that the best treatment for a patient with 'acute' cholecystitis with a calculated risk of infection is to prescribe medical treatment including antibiotics and to operate within a few days. The exception would be in patients with symptoms of acute cholecystitis for more than 1 week when it is known that the technical difficulties increase.
4. Patients with 'acute' cholecystitis without a calculated risk of infection can be safely treated by operation.
5. In conclusion it is necessary to emphasize that surgery on a tense inflamed gallbladder requires technical competence and experience.

IN accordance with the underlying pathologic principles, surgical treatment may be directed toward removing or destroying the bleeding varix, reducing so far as possible the amount of blood entering the portal circulation or increasing the collateral channels to such an extent that the portal hypertension and stasis will be relieved. While the first is not altogether a surgical impossibility, it would be a decidedly dangerous procedure. Cauterization of the varices through the esophagoscope is the only method by which it has been attempted, and so far this has met with little success. Another method of attack would be to ligate the coronary vein or group of veins between the cardia and the trunk of the portal vein, but the feasibility of this procedure is open to question. The second possibility, that of reducing the amount of blood entering the portal circulation, involves removal of the spleen, which contributes about 20 per cent of the total portal stream. This has already given good results in selected cases.

Considering that the whole tendency of portal cirrhosis is to divert the stream of portal blood away from the liver, leaving the arterial blood to provide for the parenchymal requirements, the most logical and effective method of dealing radically with the embarrassed portal circulation would doubtless be to perform a simple Eck fistula. By this means the portal hypertension would be relieved, stasis immediately abolished, and the development of varices arrested. The ideal procedure would be side-to-side anastomosis of the portal vein and inferior vena cava without ligating any trunks. This would not interfere with any other blood already reaching the liver. Although Eck fistulas have been tried at various times, the resultant uniform failure seems to be entirely due to difficulties in the operation itself. Provided a satisfactory technic can be evolved, such as that employed by Mann and his associates in their experimental work with Eck fistula on dogs, there is no reason why in suitable cases it should not be successful.

Prognosis after portocaval anastomosis: a 15-year follow-up

R. WINDLE AND J. H. PEACOCK*

SUMMARY

A 15-year follow-up of 57 patients who underwent portocaval anastomosis is reported. Twenty-seven patients were still alive and the progress of these and of those who died is followed.

The young cryptogenic cirrhotic with no encephalopathy, normal liver function tests and absence of portal vein mural thrombus at the time of operation is best benefited.

The only factor from the series to suggest a poor prognosis is deterioration in liver function in the post-jaundice cirrhotic, and the development of encephalopathy in cryptogenic cirrhotics suggests a poor long term prognosis, but its onset is not related to the time before death.

CIRRHOSIS, by distortion of the intrahepatic portal vascular bed, gives rise to portal hypertension, and the portal flow through the liver is reduced to 13 per cent (McIndoe, 1928); the rest bypasses the liver along natural portal-systemic anastomoses, one existing in the lower oesophagus between branches of the left gastric vein and those of the azygos, intercostal and diaphragmatic veins. Haemorrhage from varicosities in these veins in the oesophageal wall in portal hypertension accelerates death in 30 per cent of cirrhotics (Truelove, 1972), and the immediate mortality of bleeding has been stated to be as high as 54 per cent (Hislop et al., 1966).

Portocaval anastomosis should relieve the portal hypertension with usually minimal but unpredictable deterioration in hepatic function, depending on the reduction in hepatic blood flow following the operation (Nardi, 1955; McDermott, 1965).

Portocaval anastomosis has been performed in Bristol for intrahepatic portal obstruction since 1950. This report is concerned with the patients in whom the operation was performed more than 15 years ago in order to ascertain the late effectiveness of anastomosis in stopping bleeding and the resultant side effects.

Patients

During the period 1950–7, 57 patients underwent end-to-side anastomosis of the portal vein to the inferior vena cava at Bristol Royal Infirmary for portal hypertension secondary to intrahepatic disease. Virtually all had experienced one or more severe haematemeses, 2 patients had asymptomatic varices and another had presented with associated iron deficiency anaemia. All had been shown to have oesophageal varices on barium swallow studies or oesophagoscopy, and after 1952 the patency of the portal vein was demonstrated by percutaneous splenoportography (Walker et al., 1953), and in those who had previously had a splenectomy by operative portal venography.

The aetiology of the liver disease in the majority was unknown (*Table I*). There were 35 males and 22 females, their ages ranging from 7 to 57 years (average 33 years) at the time of operation (*Fig*. 1).

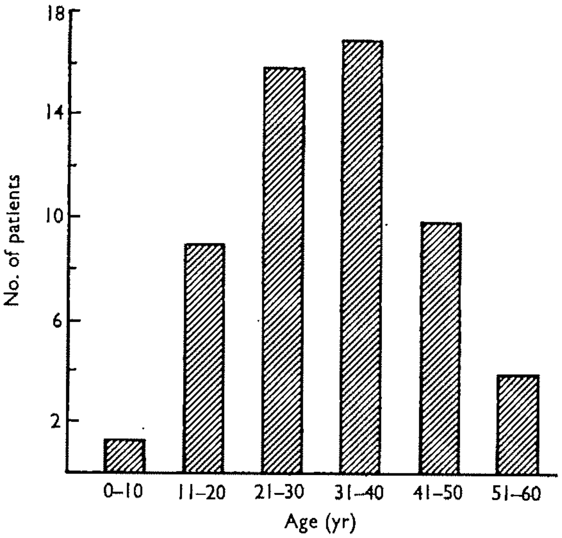

Fig. 1. Age at operation.

Table I: AETIOLOGY OF THE CIRRHOSIS

Aetiology:	No. of cases:
Unknown (cryptogenic)	38
Post-jaundice	9
Alcoholic	6
Bilharzia	1
Wilson's disease	1
Primary portal fibrosis	2
Total	57

Selection of patients for operation was on age—all the patients submitted to operation being under 60 years of age—the absence of clinical jaundice and a serum albumin of greater than 3 g/100 ml, regardless of other biochemical data.

The operative technique has been described (Walker, 1959); operative saline manometry of the portal vein pressure was performed, and if intraportal mural thrombus was found it was removed unless endothelialized and the lumen adequate.

* One died at 18 years.

Results

Four patients died in hospital in the postoperative period, an operative mortality of 7 per cent. Three of these patients died from hepatic failure and the remaining patient, in whom thrombus had been removed from the portal vein at operation, developed thrombosis of the shunt and died from further haemorrhage.

Ten patients had thrombus in the portal vein at operation (*Table II*); 4 of these developed proved shunt thrombosis and another patient had probable shunt thrombosis during the period of follow-up.

Twenty-five patients have subsequently died and one is untraceable, leaving 27 patients alive at 15 years (48·2 per cent). Of these, a further 5 have died between 15 and 20 years (2 of liver failure and one each from myocardial infarction, bleeding peptic ulcer and nephrotic syndrome) and are counted alive in this series. Four patients are alive and perfectly well at 21 years. The age of the survivors at operation was 10·1 years younger than that of the non-survivors (*Table III*).

Preoperatively the average serum bilirubin levels of the operative non-survivors, 15-year non-survivors and 15-year survivors were 0·5, 0·7 and 0·5 mg/100 ml respectively. One patient who was alive at 15 years had a level raised above normal preoperatively, but 8 patients who died within 15 years of the operation had abnormally raised serum bilirubin levels. Average serum alkaline phosphatase levels were 18 King Armstrong units/100 ml for the group of operative non-survivors, 14·5 King Armstrong units/100 ml for the group of 15-year non-survivors and 11·5 King Armstrong units/100 ml for the group of 15-year survivors. Four patients in the last group had abnormally raised levels preoperatively, whereas 7 in the group of patients not surviving to 15 years had abnormally raised levels. As stated before, all the patients had serum albumin levels greater than 3 g/100 ml and there was no significant difference in the albumin levels of the three groups.

In 68 per cent of the non-survivors the cause of death was hepatic failure (*Table IV*). Portal-systemic encephalopathy has occurred in 21 of the operative survivors (38 per cent), 13 having since died, but only 2 of these 13 were unable to work after the operation. Only patients over the age of 30 years at the time of operation were affected by encephalopathy prior to their terminal illness. At the time of follow-up 2 were unable to work due to encephalopathy; the other 6 had experienced mild bouts but 3 of them were totally free of encephalopathy when seen (*Table V*). Ten patients (19 per cent) developed encephalopathy within 5 years of the operation, and a further 8 did so in the next 5 years. Unfortunately many of the patients were given high protein diets during the early postoperative phase. This was revised when it became known that such diets predisposed the patients to portal-systemic encephalopathy.

Further haemorrhage has occurred in 8 patients, causing 1 operative and 2 later deaths (*Table VI*). The 2 patients who survived bleeding from recurrent varices had both undergone splenectomy prior to the shunt and were treated by oesophageal transection. Neither has bled since and one has no demonstrable varices at 15 years. One non-survivor had asymptomatic varices demonstrated at autopsy. Seventeen of the survivors who had not had further haemorrhage have been checked radiologically or by oesophagoscopy for varices, which have been found in 2.

Peptic ulceration has been demonstrated in 8 patients, of whom 2 had ulcers preoperatively, giving a post-shunt incidence of 12 per cent (*Table VII*).

Five patients have developed diabetes mellitus and 2 haemochromatosis since operation. No operative survivors had any significant anaemia, neutropenia or thrombocytopenia.

Considering the results in each aetiological group, 22 of the 34 patients with cryptogenic cirrhosis who survived the postoperative period (64 per cent) were alive at 15 years. Eight died of hepatic failure, their liver function deteriorating as shown in *Figs.* 2 and 3, and one each of respiratory complications, pyosalpinx, peptic ulcer haemorrhage and cardiac failure. The deaths were evenly distributed over the 15 years since operation (*Figs.* 4, 5), and their relationship to the age at operation is shown in *Table VIII*.

Ten of these non-survivors had experienced bouts of encephalopathy but all but 2 had been able to work after the operation. Of the 22 survivors with cryptogenic cirrhosis, all but one (with gross encephalopathy) were working at 15 years (*Table V*), 2 had mild encephalopathy but a total of 16 had experienced no postoperative encephalopathy. Of these 22 patients, the liver function tests showed no change after operation in 9, deterioration with subsequent recovery in 6 and deterioration without remission in 5 (*Figs.* 2, 3); there was insufficient data on the remaining 2.

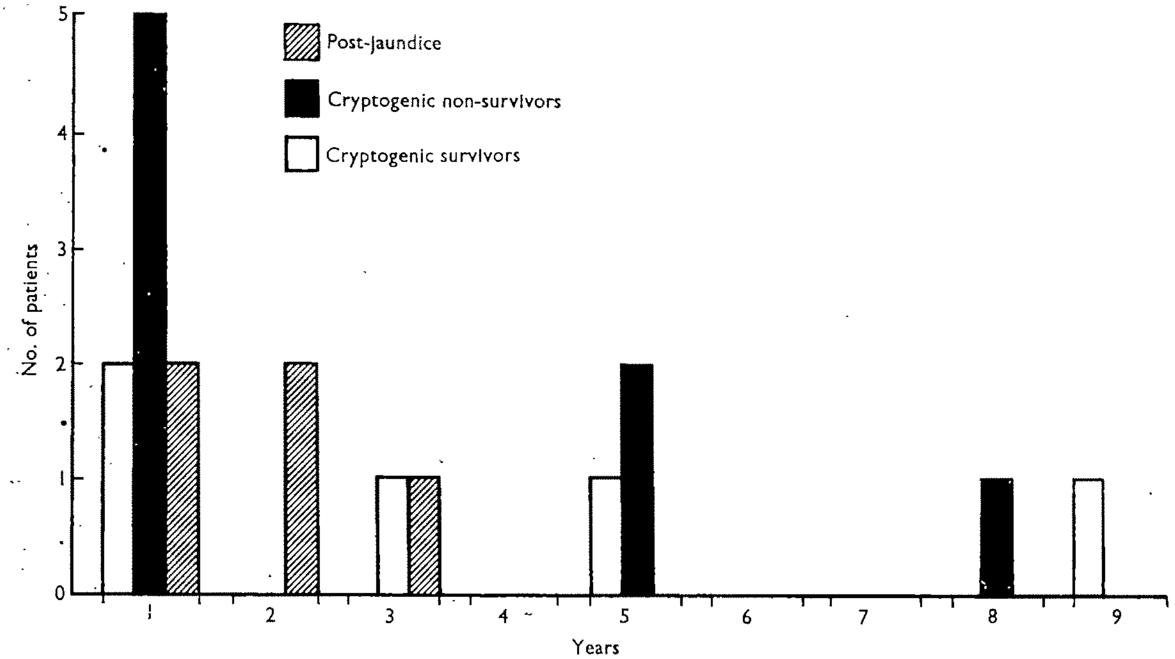

Fig. 2. Time between onset of irreversible liver decompensation and death or time of follow-up.

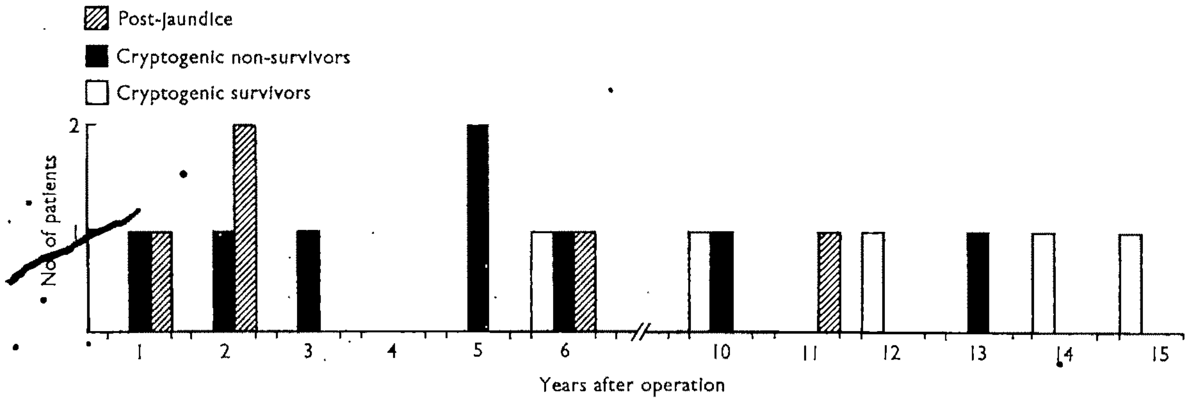

Fig. 3. Time between operation and onset of liver decompensation.

All 9 patients with a history of jaundice prior to their cirrhosis were dead by 13 years (*Fig.* 4). At operation they were between 19 and 55 years old (average 39·5). Five patients died of liver failure, and the others of bleeding varices, aortic aneurysm, carcinoma of the pancreas and suicide. The relationship of survival to age at the time of operation is shown in *Table VIII*, and the relationship of liver failure to the operation and to subsequent death in *Figs.* 2 and 3. Only 2 patients had encephalopathy at any time prior to the terminal illness and 6 patients could work after their operation.

Six patients had a history of excessive alcohol intake. One was untraceable, one died of liver failure in the first year and one continued drinking and died of liver failure in the third year after operation. Three are still alive; one now incapacitated by encephalopathy, one having mild encephalopathy and fluctuating liver function tests which were normal at the time of follow-up and one with neither encephalopathy nor liver decompensation (*Table V*). The latter 2 still appear to be drinking alcohol.

The patient with bilharzia had normal liver function at 15 years but was developing nephrotic syndrome (from which he has since died). One patient with Wilson's disease died of liver failure at 3 years, and of the 2 with portal fibrosis, one died at 6 years after operation and the other is alive and well.

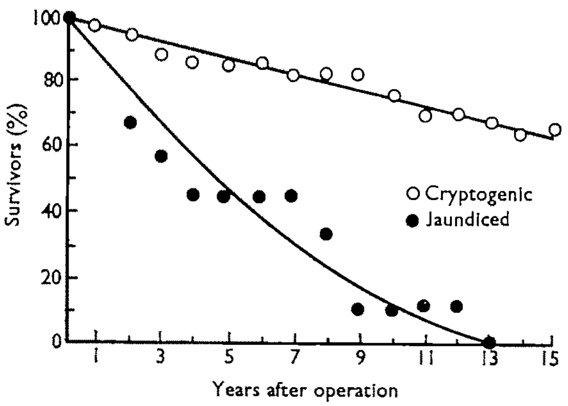

Fig. 4. Proportion of operative survivors against time.

Discussion

Without operative intervention, up to 63 per cent of adults bleeding from oesophageal varices will bleed again during the first year of follow-up (Sherlock, 1964). In 15 years of follow-up, 4 (7 per cent) of our patients have had further bleeding owing to recurrent varices after the shunt operation. Of the 4, 2 have been controlled by further surgery to the oesophagus. Forty-eight had no recurrent haemorrhage, and of these, 40 came to autopsy or were investigated to see whether they had recurrence of oesophageal varices. These were found in 3 patients, giving a total recurrence rate of 12 per cent in the 48 patients investigated.

The problems that portocaval anastomosis creates for the patient are well known. Other than an increase in the burden of hepatic decompensation, portosystemic encephalopathy, diabetes mellitus and peptic ulceration as well as other less common problems including haemosiderosis and pulmonary complications can occur (Grace and Balint, 1966; Sherlock et al., 1970). The operative mortality of 7 per cent in this series is within that quoted by Sherlock (1971) of 5 per cent and by Hunt (1967) of 8 per cent for elective portocaval anastomosis, in distinction to the much higher figure of 25 per cent (Sherlock, 1971) for emergency portocaval anastomosis.

Portal-systemic encephalopathy, widely quoted as the major limiting factor in the success of portocaval anastomosis, occurs in as many as 48 per cent of patients to a measurable degree (Sherlock et al., 1970)

Table VIII: RELATIONSHIP OF SURVIVAL TO AGE AT OPERATION

	Age at operation (yr)				
Group	11–20	21–30	31–40	41–50	51–60

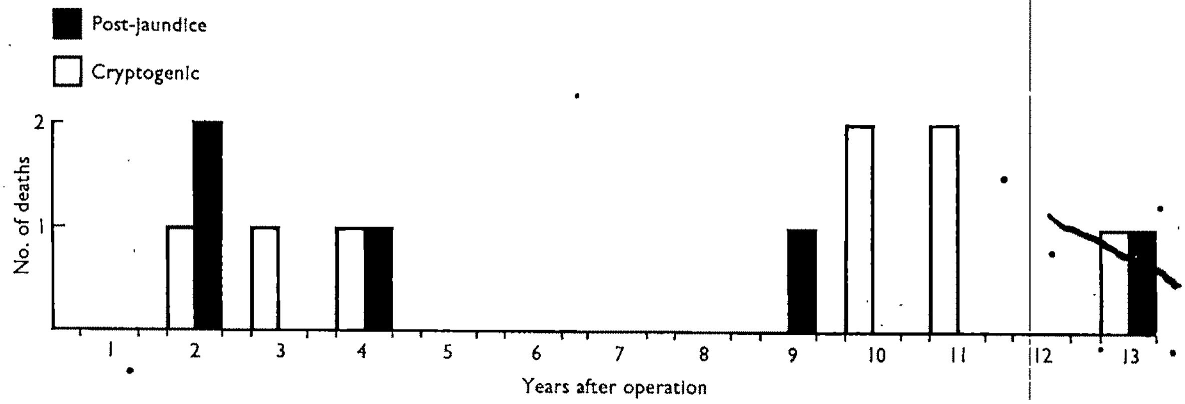

Fig. 5. Number of deaths of patients from hepatic failure per year after operation.

and to a severe degree in from 15 per cent (Grace et al., 1966) to 37 per cent (Read et al., 1961). Of the 53 operative survivors, 21 patients (38 per cent) developed portal-systemic encephalopathy, the onset being distributed over the 15 years following surgery, with a predominance during the first 5 postoperative years. However, only 4 (8 per cent) were persistently kept from working by it. Portal-systemic encephalopathy was a worse problem in the cryptogenic cirrhotic group, 47 per cent of which developed the complication, as opposed to the older post-jaundice cirrhotic group of which only 28 per cent developed encephalopathy prior to their terminal illness. This does not agree with our observation or that of others (Read et al., 1961) that portal-systemic encephalopathy occurs more often in higher age groups, and suggests that portal-systemic encephalopathy and liver biochemistry deterioration do not occur together in the post-jaundice group.

Sixty-eight per cent of our patients died of hepatic failure. Eight of the 34 patients with cryptogenic cirrhosis died of liver failure, with a further 5 showing deterioration of liver function. The onset of liver failure began at a variable period postoperatively but in 75 per cent it became manifest during the first 6 years. A greater proportion (5 out of 9) of post-jaundice cirrhotic patients died of hepatic failure, 60 per cent of them developing it within 2 years of the operation. This deterioration of liver function in the early years after portocaval anastomosis has been observed previously by Sherlock et al. (1970) and demonstrates what is often the progressive nature of cirrhosis following hepatitis.

In predicting the patients best benefited by portocaval anastomosis it is considered that the younger the patient and the less the hepatic decompensation, the better is the prognosis postoperatively, jaundice, low serum albumin and portal-systemic encephalopathy being contraindications to the operation (Sherlock, 1964). The young cryptogenic cirrhotic was best benefited in our series; 82 per cent of those under 30 years at operation were alive at 15 years, while none of the patients over 40 years at operation was alive at 15 years (*Table VIII*). The patients who had post-jaundice cirrhosis and who were of ages comparable to the non-surviving group of cryptogenic cirrhotics did no better, all dying by 13 years after the operation.

The patients with alcoholic cirrhosis, who usually progress well after the operation if drinking is stopped (Sherlock, 1971), did well in the small series we present here, 3 out of 5 patients being alive at 15 years and the 2 least incapacitated by encephalopathy still drinking alcohol. However, of 15 patients, all alcoholic cirrhotics, who have undergone portocaval anastomosis since 1957 in Bristol, 11 are traceable and 9 of these have died of liver failure within 5 years of operation.

Patients with any degree of liver decompensation are not usually submitted to elective portocaval anastomosis, and it can be seen from our series that the patients with an abnormally raised serum bilirubin level have not progressed as well as those with normal bilirubin levels. Abnormally raised alkaline phosphatase levels in the serum appear to be of less significance.

Patients who had thrombus in the portal vein at operation did not progress well after the operation; 30 per cent were alive at 15 years and 80 per cent of them had rethrombosis of the shunt. This even applied when the thrombus was easily removed from the portal vein at operation.

The progress of the patient after his portocaval anastomosis allowed some prediction of his ultimate prognosis. If the patient had further haemorrhage, whether this was associated with shunt thrombosis or with a peptic ulcer, the problem was serious and even haemorrhage from peptic ulcer had a mortality of 33 per cent. Deterioration in liver function heralded a rapid deterioration in the patients who had post-jaundice cirrhosis, and commonly, but not as often, in the patients with cryptogenic cirrhosis. However, portal-systemic encephalopathy had a prognostic significance only in the patients who had cryptogenic cirrhosis, as 10 of the 12 operative survivors in the latter group who were dead by 15 years had portal-systemic encephalopathy, but there was little relationship to time, as those with portal-systemic encephalopathy at 10 years were all alive at 15 years.

Acknowledgements

We acknowledge with gratitude the fact that these patients are the original series of Professor R. Milnes Walker (Walker et al., 1961).

We also acknowledge the help of Dr P. D. Mulcahy, Dr G. M. Colson, Dr J. N. MacCaig, Dr P. J. Toghill and Dr M. J. Whelton in tracing and arranging investigations on their patients included in this series.

The effect of acute ethanol administration on the exocrine pancreatic secretion of the pig

I. C. WHEATLEY, G. O. BARBEZAT, ROSEMARY HICKMAN
AND J. TERBLANCHE*

SUMMARY

The acute effect of intravenous and intragastric alcohol on exocrine pancreatic secretion was studied in pigs with chronic pancreatic and gastric fistulas. A new H-type pancreatic cannula was designed for the study.

With intravenous alcohol and the gastric fistula open, increased gastric acid secretion occurred but pancreatic enzyme output was inhibited. When acid was allowed to enter the duodenum by closing the gastric fistula, intravenous alcohol produced a secretin-like effect of increased pancreatic volume and bicarbonate secretion.

Intragastric alcohol caused an increase in volume, bicarbonate and enzyme output. This was probably due initially to direct gastroduodenal stimulation as the same response occurred following intragastric mannitol of similar volume, pH and osmolality. The subsequently sustained increase in volume and bicarbonate was possibly a secondary secretin-like response following absorption of alcohol.

It is concluded that the pig pancreas responds to alcohol as has been described in other animals. The use of a single model has allowed clarification of various phases of response invoking the effects of secretin, gastric and glucagon.

ALCOHOL abuse is the commonest cause of pancreatitis in the Western Cape of South Africa (Marks et al., 1974). The exact pathogenesis is not known despite investigations in many laboratories and in a number of models (Dreiling et al., 1952; Davis and Pirola, 1966; Janowitz and Bayer, 1971). Some workers have found that alcohol stimulates pancreatic secretion (Lowenfels et al., 1968), but depression has also been noted (Bayer et al., 1972; Mott et al., 1972; Tiscornia et al., 1973). In some studies gastric secretion was diverted from the duodenum, while in others the important secondary effect of duodenal acidification and secretin release was retained (Walton et al., 1960). The present study was designed to determine the acute effect of intravenous and intragastric alcohol on secretin- and cholecystokinin-stimulated exocrine pancreatic secretion in a uniform porcine model. It constitutes a preliminary phase of a projected study of the effect of alcohol on the chronically damaged pig pancreas, using a model developed in our laboratory (Waterworth, Bank and Terblanche, 1973).

Materials and methods

A new cannula was developed to establish a chronic pancreatic fistula in the pig (Wheatley et al., 1974). This was H-shaped and made of Fluorodur, a synthetic biologically inert plastic material (*Fig.* 1). The vertical limbs of the H were 10 cm long with an internal diameter of 1 cm and a wall thickness of 5 mm. The cross-connection was 4 cm long. For collection of pancreatic juice an inner sleeve was inserted into the limb draining the pancreatic duct.

Studies were performed on Large White × Landrace female pigs weighing 20–35 kg. Operations were conducted under sterile conditions using thiopentone sodium for induction, and nitrous oxide, oxygen and halothane for maintenance of general anaesthesia.

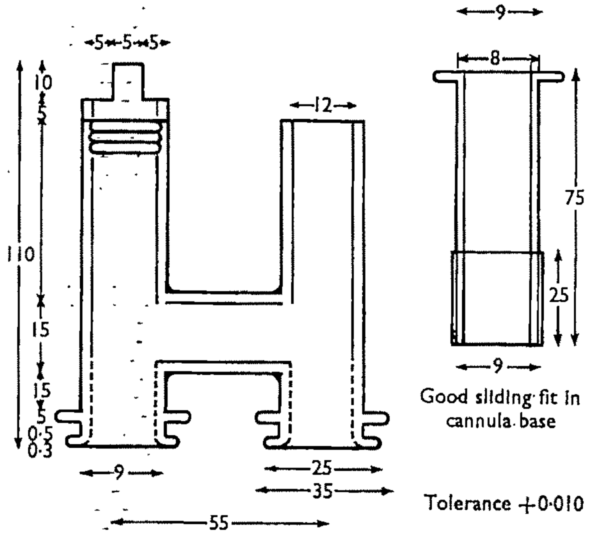

Fig. 1. Specification for manufacture of the H-shaped cannula from Fluorodur. (Lengths in mm.)

The pancreatic duct in the pig enters the medial wall of the duodenum 7–10 cm distal to both the pylorus and the common bile duct. This portion of the duodenum was divided at 3 cm on either side of the pancreatic duct and a pouch constructed by closing both ends of the free segment of duodenum. Duodenal continuity was restored by end-to-end anastomosis. One limb of the cannula was inserted into the pouch opposite the pancreatic duct, and the other limb into the duodenum proximal to the anastomosis. The

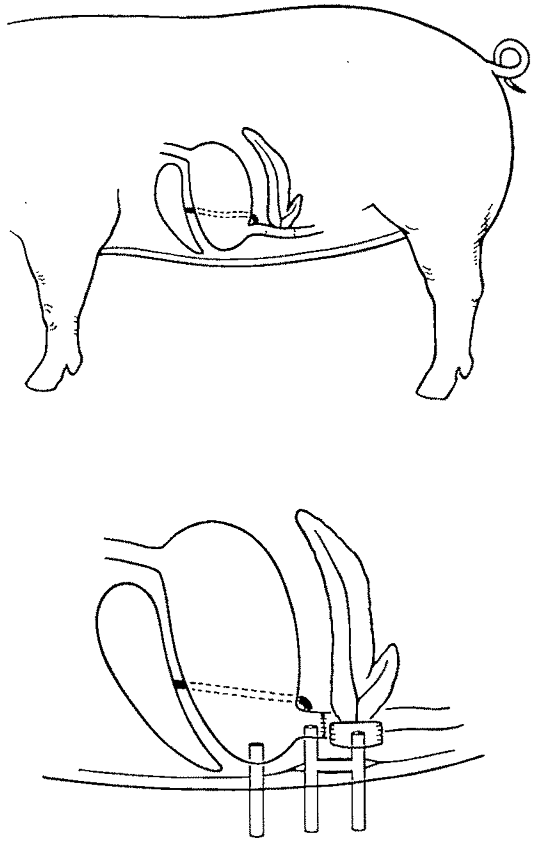

Fig. 2. Diagram showing the pancreatic and gastric cannulas in position.

cannula was retained with a purse string suture and several interrupted silk sutures holding the surrounding duodenal wall to the outer flange. Omentum was wrapped liberally around the inner ends of the cannula. The outer ends of the cannula were then brought out through the anterior abdominal wall to the right of the midline. The peritoneum was resutured deep to the cross-piece in order to retain this extraperitoneally. A gastric cannula was inserted into the most dependent portion of the stomach and brought out on to the anterior abdominal wall (*Fig.* 2). Animals were allowed a 2-week recovery period before being used for experiments.

Pigs were deprived of food but not water for 24 hours before each study. No animal was used more than twice per week and never on successive days. The pigs were supported in modified Pavlov frames during the studies, each of which lasted 6 hours. After a 30-minute basal period Boots' secretin (1 u. $kg^{-1} h^{-1}$) and cholecystokinin (1 u. $kg^{-1} h^{-1}$) suspended in 0·15 M-NaCl were infused into an ear vein at 6 ml/h using a Braun Unita 1 infusion pump (B. Braun, Melsungen, West Germany) for the remainder of the study. The dose of secretin was that found to give half-maximal pancreatic volume and bicarbonate response (K_m dose), while that of cholecystokinin was twice that producing half-maximal protein response (twice K_m dose), on a background of secretin (1 u. $kg^{-1} h^{-1}$) in preliminary studies in the pig (Wheatley, 1975). This dose of cholecystokinin provided submaximal stimulation enabling changes in pancreatic protein secretion, particularly inhibition, to be observed during the study with alcohol. Within a further 90 minutes a stable pancreatic response was observed.

One of the following treatments was then superimposed on the background hormonal stimulation.

Intravenous alcohol

Absolute alcohol (96 per cent w/v, 0·5 ml/kg) was given by constant infusion into a jugular vein catheter for 2 hours and an infusion of 0·15 M-NaCl was given into a catheter in another jugular vein. Six studies were performed in 4 pigs leaving the gastric fistula open, and 8 studies in 3 pigs with the gastric fistula closed. Control studies were performed on 4 pigs using 0·15 M-NaCl 5 instead of alcohol. Five studies were performed with the gastric fistula open, and 5 with it closed.

Intragastric alcohol

Five per cent alcohol (96 per cent w/v diluted in 0·15 M-NaCl) was infused into the stomach via the gastric cannula at the rate of 20 ml $kg^{-1} h^{-1}$ for 1 hour. The total dose of alcohol was the same as that given intravenously but it was given over 1 hour. Six studies were performed on 2 pigs. As a control study 15 per cent mannitol solution in 0·15 M-NaCl (approximately 1300 mosoml/l) was substituted for the 5 per cent alcohol. Four studies were performed on 2 pigs.

In both groups of experiments samples were collected every 15 minutes from the pancreatic and, where applicable, gastric cannulas. Pancreatic samples were measured for volume and stored on ice for estimation of bicarbonate and protein later in the day. Bicarbonate was estimated by adding 1 ml 0·1 M-HCl to 0·5 ml pancreatic juice, boiling and back-titrating to pH 7 with 0·1 M-NaOH using an automatic titrator (Radiometer, Copenhagen). Enzyme concentration was measured as total protein using the absorbance of an appropriately diluted sample at 280 nm on a Beckman spectrophotometer and comparing it with a standard bovine albumin solution. It has been shown that there is good correlation between the protein concentration of pancreatic juice and pancreatic enzyme (Keller et al., 1958). Gastric juice was measured for volume only as the degree of biliary reflux made acid estimation unreliable. Blood was taken for blood alcohol determinations at 30, 60, 120, 180 and 240 minutes after starting the alcohol infusion. For these an 'Ethyl Alcohol Stat-Pack' supplied by Calbiochem was used. Statistical comparisons were made using Student's *t*-test for unpaired values.

Results

The cannulas functioned satisfactorily for 4–5 weeks from the onset of studies, but after this time most pigs developed a small bowel fistula around the cannula. At autopsy this leak was found to occur between the

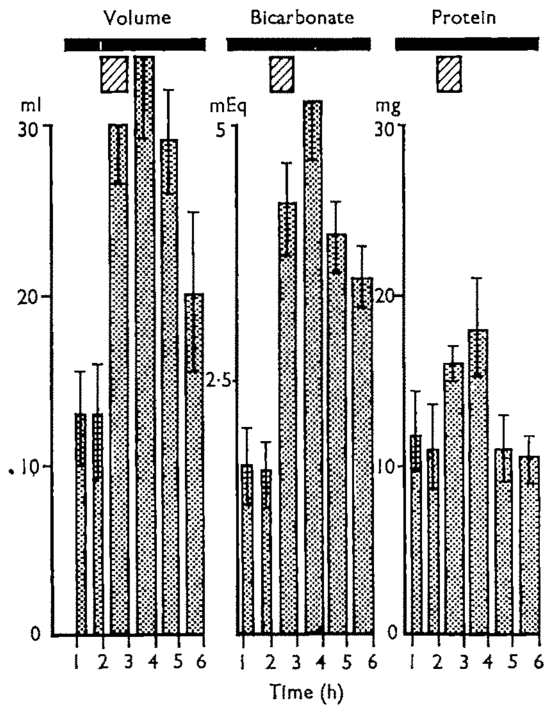

Fig. 5. Change in pancreatic secretion with intragastric alcohol.

cannula and the duodenal wall. The pancreas was histologically normal.

Intravenous alcohol

Intravenous alcohol produced the following effects. With the gastric cannula open the mean volume of gastric juice increased as alcohol was infused from 11 ± 2·5 ml to a peak of 31 ± 5·8 ml/15 min at 5 hours ($P < 0·05$) (*Fig.* 3*a*).

Owing to diversion of gastric acid away from the duodenum via the gastric cannula, there was no stimulation to pancreatic volume and bicarbonate secretion which did not vary significantly from basal (*Fig.* 3*b*). However, there was a significant depression in protein output from 11·4 ± 4·0 to 5 ± 1·5 mg/15 min ($P < 0·05$) at the end of the fourth hour of the study. This maximal depression coincided with the peak blood alcohol level which reached 0·09 mg/100 ml of blood.

In contrast, control studies with intravenous saline failed to show a depression in pancreatic protein secretion, which rose slightly from a basal level of 7·4 ± 3·2 to 10·3 ± 5·4 mg/15 min at the end of the fourth hour. This was not statistically significant.

Pancreatic secretion did not vary significantly from a mean basal volume of 6·5 ± 1·5 ml/15 min and bicarbonate secretion of 0·7 ± 0·21 mEq/15 min when saline was infused. With the gastric cannula closed (*Fig.* 4), allowing juice to enter the duodenum, intravenous alcohol caused a marked rise in mean pancreatic volume from 13·9 ± 5·0 to 30·6 ± 5·2 ml/15 min ($P < 0·05$) and in bicarbonate output from 1·6 ± 0·7 to 4·4 ± 0·9 mEq/15 min ($P < 0·01$). The peak rise was in the hour following the peak blood alcohol level. Protein output showed a rise at the start of the alcohol infusion from 15·8 ± 5·1 to 21 ± 6 mg/15 min, then fell gradually until the end of the study, but at no time was there a significant variation from basal.

Control studies with intravenous saline and a closed gastric cannula showed a slight rise in pancreatic secretion with time as basal gastric acid secretion presumably passed into the duodenum to release secretin. Pancreatic volume rose from 7·4 ± 2·7 ml to 10 ± 3 ml/15 min at the end of the study, while bicarbonate output rose from 0·85 ± 0·4 to 1·3 ± 0·5 mEq/15 min; neither increase was statistically significant. Protein also rose from 8·9 ± 3 mg to reach a peak of 11·4 ± 3 mg/15 min at the end of the fifth hour.

Intragastric alcohol

With intragastric alcohol given over 1 hour (*Fig.* 5) there was a pronounced and persistent rise in mean pancreatic volume from 12·6 ± 3·5 to 34·2 ± 5·0 ml/15 min ($P < 0·01$); bicarbonate output rose from 1·6 ± 0·5 to 5·2 ± 0·6 mEq/15 min ($P < 0·05$). In marked contrast to the study with intravenous alcohol and an open gastric cannula, there was a rise in protein output from 10·8 ± 2·2 to 17·7 ± 3·0 mg/15 min ($P < 0·05$).

It was noted that peak secretion was reached simultaneously with peak blood alcohol level 2 hours after starting the alcohol infusion via the gastric cannula (0·09 mg alcohol/100 ml blood).

Intragastric mannitol

Intragastric mannitol produced a rapid rise in pancreatic volume from 12·7 ± 1·7 to 29 ± 1·6 ml/15 min ($P < 0·05$) at the end of the third hour of the study, but then fell quickly towards the basal level so that at the end of the fourth hour it was down to 19·5 ± 4 ml/15 min, and at the fifth and sixth hours was 17 ± 4·5 and 14 ± 3 ml/15 min respectively.

This early peak and rapid fall contrasted with the change produced by intragastric alcohol where a peak at the fourth hour of 34·2 ± 5·0 ml/15 min was significantly higher than the level produced by mannitol of 19·5 ± 4 ml/15 min ($P < 0·05$) and persisted longer (*Fig.* 4). A parallel effect occurred with bicarbonate, which rose from 1·47 ± 0·3 to 4·1 ± 0·3 mEq/15 min ($P < 0·05$), then fell to 2·6 ± 0·5, 2·4 ± 0·6 and 1·8 ± 0·6 in successive hours, compared with the more pronounced and persistent rise seen with intragastric alcohol. The effect was repeated with protein, which rose from 11·4 ± 2·5 to 24·5 ± 7·5 mg/15 min, then fell to 19·4 ± 4·9, 14·9 ± 6 and 12 ± 4·5 mg/15 min in subsequent hours.

Discussion

In previous work on the effect of intravenous alcohol in the pig which was performed in antrectomized animals an increase in pancreatic volume and amylase output was noted (Hong and Magee, 1970). The authors concluded that the role of ethyl alcohol as a pancreatic stimulant was not clear. The present study is a composite investigation of the effects of intravenous and intragastric alcohol in a standard physiological pig model in one laboratory. The pig has not been commonly used for pancreatic studies, but has proved to be satisfactory for short term physiological studies. An attempt is being made to develop a long term pig model although rapid growth of the animals may render them unmanageable. The cannula will also require modification, perhaps by use of a flexible cross-connection to minimize leaks.

Alcohol has been shown to have two stimulatory effects on gastric acid secretion. Ingested alcohol stimulates the release of gastrin from the antrum, causing increased acid secretion (Woodward et al., 1957). Alcohol is also rapidly absorbed and then exerts its second systemic action, producing a further increase in gastric acid. This appears to be independent of the gastrin-releasing mechanism of intragastric alcohol and is blocked by anticholinergics (Hirschowitz et al., 1956). In this study a marked stimulatory effect of intravenous alcohol on gastric volume output was confirmed.

The increased acid produced by these two mechanisms passes to the duodenum where it causes the release of secretin (Bayliss and Starling, 1902; Epstein and Williams, 1961; Valenzuela et al., 1969), which in turn stimulates the pancreas to secrete bicarbonate and water. This is the main indirect or gastric-mediated response to alcohol. The present study has confirmed that this secretin-like effect is not a direct effect of alcohol on the pancreas, as the intravenous administration of alcohol with the gastric fistula open did not increase secretion of bicarbonate and water. On the other hand, when the gastric fistula was closed and acid allowed to enter the duodenum a typical pancreatic secretin-like response was observed.

The second effect of alcohol on the pancreas is direct. Gastrin is a weak stimulant of pancreatic enzyme secretion in the dog (Stening and Grossman, 1969) and possibly in man (Wormsley et al., 1966; Petersen and Berstad, 1973). The pancreatic protein response produced by intragastric alcohol would suggest that alcohol released gastrin in the pig and that this in turn acted on the pancreatic acini. The early rise in secretion noted after the administration of intragastric mannitol suggests that this effect may be partially osmotic. Release of cholecystokinin in the small bowel is also a possibility.

A third effect of alcohol on the pancreas is direct depression of enzyme secretion (Tiscornia et al., 1973; Solomon et al., 1974). This was confirmed in the present study where intravenous alcohol depressed pancreatic protein secretion when the gastric fistula was left open. The failure of intravenous alcohol to depress protein secretion in the experiments with the gastric cannula closed may be due to endogenous secretin potentiating the effect of the background infusion of a submaximal dose of cholecystokinin on pancreatic enzyme secretion, as potentiation between these two hormones is known to occur (Wormsley, 1969). There was no evidence of a diminished volume secretion by the pancreas, and no support was found for alcohol producing obstruction to pancreatic flow (Lowenfels et al., 1968). Of the gut hormones, glucagon is known to depress pancreatic protein output (Dyck et al., 1970). In other studies in our laboratory, intravenous glucagon has been shown to depress pancreatic enzyme secretion in secretin-stimulated pigs and in secretin + cholecystokinin-stimulated humans (Waterworth, Barbezat and Terblanche, 1973). One explanation for the depressed secretion noted with intravenous alcohol with the gastric cannula open may be a glucagon-mediated inhibition, as shown in *Fig.* 6. This will require further investigation. The response of the autonomic nervous system also warrants further examination in view of recent studies of the effect of vagotomy on pancreatic secretion (Konturek et al., 1974).

The exact role of alcohol in the pathogenesis of acute pancreatitis remains a mystery. Recent work has shown that dogs lose their ability to depress pancreatic secretion with alcohol when they are chronically fed on alcohol (Sarles et al., 1973). This was particularly evident with regard to protein secretion, and it was suggested that this protein, in relative excess, could form plugs in the pancreas. Calcium was low in the juice after alcohol ingestion, but this could be a result of precipitation in the protein plugs.

Other studies have shown a decreased incorporation of ^{32}P into phospholipids by the rat pancreas after alcohol ingestion; if the alcohol intake was prolonged the pancreas failed to recover normal function (Orreggo Matte et al., 1969). Similarly, ultrastructural damage to pancreatic tissue has been demonstrated after chronic alcohol ingestion (Darle et al., 1970). These changes are not unlike those seen with alcoholic damage to the liver, suggesting a direct toxic effect.

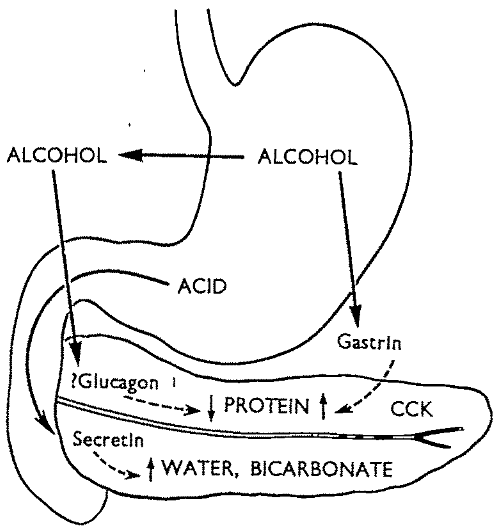

Fig. 6. Postulated mechanism for the actions of alcohol on pancreatic secretion.

Further understanding of the pathophysiology of alcohol and pancreatic function may provide the answer to alcohol-induced pancreatitis.

Acknowledgements

The advice and encouragement of Professor J. H. Louw are gratefully acknowledged. The studies were performed with the help of the staff of the J. S. Marais Surgical Laboratory, and Mesdames J. Fourie, J. Green, C. Rose-Innes and M. van Heerden performed the biochemical estimations.

Financial assistance was received from the Cape Provincial Administration, the Medical Research Council of South Africa and the Herman and Caporn Bequests to the University of Cape Town.

Mr D. Stewart of the Biomedical Engineering Department of Groote Schuur Hospital made the cannulas.

The effect of heparin and of acid-citrate-dextrose solution on screen filtration pressure of blood in experimental hypotension

B. J. PARDY AND H. A. F. DUDLEY*

SUMMARY

Anticoagulation with heparin may not always adequately protect an ischaemic vascular bed. A screen filtration device has been employed to study the in vitro actions of acid-citrate-dextrose (ACD) and heparin on blood from the dog in haemorrhagic shock. With both anticoagulants, blood obtained during shock caused greater filter obstruction than blood taken before shock. However, the increased obstruction was nearly four times greater with heparinized blood than with acid-citrate-dextrose blood. These findings suggest that the anticoagulant action of heparin may be markedly diminished in low blood flow states.

It is the standard practice of many surgeons to heparinize a regional vascular bed in which circulatory arrest is to occur on the premise that clotting will then be prevented. However, there is both clinical and experimental evidence that the use of heparin is not always successful: the lower limb sometimes does not recover after aortic cross-clamping, and although embolization may be blamed, clot is not always found; in rat kidney (Diethelm and Wilson, 1971) and adrenal (Kovács et al., 1966) and in rabbit brain (Ames et al., 1968) heparin has been ineffective in preventing microcirculatory obstruction.

Thus, it seemed important to establish if heparin effectively inhibited the tendency for fibrin to form under conditions of hypoperfusion. We have studied the changes in screen filtration pressure (SFP) of blood which occur with a standard shock preparation in the dog. The method is an indirect indication of any tendency of circulating blood to cause obstruction in the microcirculation, but is obviously influenced by many factors. For example, blood without anticoagulant and tested immediately causes little or no obstruction to a screen filter of 20 μ pore size (Swank, 1962); however, blood stored in acid-citrate-dextrose (ACD) for 3 weeks produces a marked obstruction, an effect thought to be the result of aggregation of platelets and leucocytes (Swank, 1961). The high SFP of ACD blood takes more than 2 days to develop, by comparison with 16–24 hours in heparinized blood (Swank, 1961). In that platelet aggregation can be induced easily in citrated plasma (Dhall et al., 1969), these observations suggest that the early rise in SFP in heparinized blood is likely to be caused by the development of fibrin. For a variety of reasons heparin is a relatively weak inhibitor of fibrin formation; indeed, heparinized blood cannot be stored for any length of time because of its tendency to produce fibrin clots (Mollison, 1972a). Finally, in relation to normal blood, red cell aggregation is unlikely to be important as a cause of screen filter obstruction (Dhall et al., 1969).

Variable results have been found for SFP in experimental exsanguination. On the one hand, blood without anticoagulant is said to cause marked filter obstruction, possibly because of an increased tendency of platelets and white cells to adhere rather than on account of the presence of preformed aggregates (Swank, 1962); on the other hand, a change in SFP has not been found in some breeds of dog (Swank et al., 1974). In the light of the effect of ACD and of heparin on normal blood, and of preliminary studies which had suggested increased SFP in blood from the dog in shock, a comparison was made between the two anticoagulants.

Materials and methods

The screen filtration technique was essentially that of Swank (1961). The 20 μ filter was mounted in a stainless steel block heated to 37 °C; blood or saline was forced through the system with a mechanical ram attached to a plastic syringe. Pressure was transduced from a side-arm with a strain gauge and traced on a chart recorder. A 2-ml syringe driven at a flow rate of 1 ml/7 sec and a 5-ml syringe at 1 ml/3·8 sec were used for blood and saline respectively. The filter was calibrated with 2 ml of saline; 0·7 ml of blood (5 sec filtration) was then passed through, followed by a further 2 ml of saline. The difference between the two saline pressures gives an indication of the degree of obstruction produced by the blood.

Preparation of heparinized and ACD blood was standardized. A heparin concentration of 3 i.u./ml is required to prevent normal human blood from clotting *in vitro* (Mollison, 1972b), and preliminary studies confirmed that this level would prevent change in SFP for up to 1 hour at 37 °C. Consequently, and because of the expected greater coagulability of the blood of the experimental animal, a level of 5 i.u./ml was decided upon. Heparin Injection (mucous) BP without bacteriostatic (Paines & Byrne Ltd) containing 1000 i.u./ml was diluted 1 : 30 with normal saline; 110 μl were then inserted into a siliconized 2-ml syringe (Silicone Fluid MS 1107, Hopkins & Williams Ltd). A similar quantity of ACD (NIH Solution A) (Mollison, 1972c) was placed in a further 2-ml syringe. Blood obtained by needle puncture of the femoral vein into a siliconized 5-ml syringe was

Table I. CHANGES IN ARTERIAL PRESSURE AND MIXED VENOUS Po_2 AND pH

	Control 1	Control 2	Shock	Post-shock 4 h	Post-shock 8 h
Arterial pressure (mm Hg)	201 ±9·7	202 ±11·8	88 ±10·2	184 ±21·9	186 ±20·2
Pvo_2 (mm Hg)	51 ±3·0	48 ±2·1	24 ±4·6	44 ±1·5	43 ±2·1
pHv	7·406 ±0·011	7·402 ±0·020	7·168 ±0·051	7·362 ±0·033	7·390 ±0·016

Results given as mean ±s.d.

aspirated into the prepared syringes in such a quantity as to give a final heparin concentration of 5 i.u./ml in blood at a PCV of 45 per cent. The plasma ACD concentration was approximately that of ACD in whole blood also at a PCV of 45 per cent, that is 1 : 9. The two samples were placed on a mixing table for 1 minute and then in a waterbath at 37 °C. After 1 hour SFP was measured. Coincidentally, a mixed venous blood sample for hydrogen ion activity (pH) and oxygen tension (Pvo_2) was withdrawn from a pulmonary artery catheter and measured with a micro-electrode system. Shock was induced in 5 greyhounds of mean weight 27 kg. The procedure is summarized in *Fig.* 1.

Filter resistance was expressed as the fourth root of the measured pressure. Statistical analysis was by the Walsh test for non-parametric paired data (Siegel, 1956).

Results

Changes in mean arterial pressure and mixed venous Po_2 and pH are seen in *Table I*. The comparison between blood treated with ACD and with heparin is shown in *Fig.* 2. At all stages heparinized blood caused greater obstruction than did ACD blood. The pooled values in the control periods differ significantly from each other ($P = 0·005$). During shock SFP is increased; 0·38 ± 0·14 (mean ± s.d.) for ACD blood, and 1·49 ± 0·60 for heparinized blood. The incremental ratio is 1 : 3·9, that is, heparin is nearly four times less effective than ACD in the prevention of increased filter obstruction by blood from the dog during shock.

Discussion

These results show that change in SFP during and after haemorrhagic hypotension in the dog is dependent upon the anticoagulant used. Heparin is associated with a marked increase. Although the evidence is, as already discussed, indirect, it is probable that the obstruction is the result of fibrin formation.

There are a number of factors which might cause this ineffectivity of heparin. Increased thromboplastin activity nullifies its anticoagulant action (Jaques, 1963); platelet consumption with thromboplastin release is a known accompaniment of hypovolaemic hypotension. Paracoagulation of soluble fibrin monomer complex by lysosomal protein fraction of polymorphonuclear leucocytes may also be of significance because heparin at the concentration used does not prevent this form of precipitation of fibrin (Hawiger et al., 1969). Further, lysosomal enzymes are released during haemorrhagic shock (Clermont et al., 1972) and these directly antagonize heparin (Stamm, 1966). Mild acidity interferes with the anticoagulant activity of heparin (Jensen et al., 1948; Crowell and Houston, 1961; Hardaway et al., 1964), but in the current study high SFPs were present at normal pH. Finally, heparin consumption or degradation may interfere with its anticoagulant properties in the animal in shock. Whatever the cause of the increased SFP of heparinized blood in the preparation studied, the evidence is presumptive that a microcirculatory problem might still persist despite the use of heparin. The same may well be true for a regional circulation in which the flow of blood is arrested. A reassessment of heparin for both general and regional use seems called for.

Acute segmental ischaemic enteritis in Thailand

THEODORE P. WELCH AND SOMSAK SUMITSWAN*

SUMMARY

A disease characterized by segments of ischaemic small intestine has been recognized in northern Thailand over the past decade. The clinical features and appearance of the diseased intestine are described. Most of the patients were treated by surgical resection of the affected bowel. The overall mortality was 14 per cent. Recently, some patients have been successfully treated by non-surgical means. The aetiology of the disease is still unknown.

THE first 5 cases of acute segmental ischaemic enteritis recognized at the Chiang Mai University Hospital were described by Headington et al. in 1967. Since that time this disease has been encountered in several more patients. This paper describes 50 cases seen between 1962 and 1972. The following case history illustrates the typical clinical picture.

Case report

A 5-year-old Thai boy was admitted on 21 April 1970 with a 4-day history of generalized abdominal pain accompanied by fever for 3 days. The day before admission he had developed diarrhoea with frank blood. On admission his pulse was 160/min and he was clinically dehydrated. He had a distended, silent abdomen. There was no localized tenderness. Rectal examination was normal apart from the fact that he had liquid, bloody diarrhoea.

Investigations revealed the following: haemoglobin 13·3 g per cent, haematocrit 42, white cell count 8300/mm^3, CO_2 reserve 4 mEq/l. An abdominal X-ray showed dilated small bowel and thickened bowel wall of the lower jejunum.

The patient's dehydration and acidosis were corrected preoperatively. At laparotomy it was found that apart from the first 90 cm of jejunum all the jejunum and ileum showed ischaemic changes. The bowel wall was a deep red colour and showed no evidence of peristalsis. It was felt that the patient could not survive if all the affected intestine was resected, so the intestine was decompressed and the abdomen closed. The patient was treated with intravenous tetracycline (250 mg 6-hourly) and hydrocortisone (100 mg 6-hourly). He made a good recovery. His diarrhoea stopped after the operation and he was discharged on the twelfth postoperative day. He was seen for follow-up in September 1971 and appeared well. He was well nourished and had normal bowel function. His haemoglobin was 11·5 g per cent.

Patients and methods

The clinical records of 50 patients were analysed. The diagnosis of segmental ischaemic enteritis was made on clinical, radiological and histological grounds. The ages of the patients studied ranged from 1 year and 10 months to 60 years. Seventy per cent of the patients were males (*Table I*).

Symptoms and signs

The duration of symptoms preceding admission ranged from 1 to 10 days with an average of 2·9 days. The first symptom was usually generalized abdominal pain, which was soon followed by diarrhoea and fever. In 74 per cent of the cases the diarrhoea had frank blood, either from the outset of the diarrhoea or from soon afterwards. Nausea and vomiting were commonly present. The admission symptoms are tabulated in *Table II*. None of the patients gave a history of recent abdominal trauma or a period of hypotension preceding the onset of symptoms.

Table I: AGE AND SEX DISTRIBUTION

	Males		Females		Total	
Age group	No.	%	No.	%	No.	%
0–5	6	12	1	2	7	14
6–9	13	26	1	2	14	28
10–19	9	18	4	8	13	26
20–29	5	10	1	2	6	12
30–39	1	2	3	6	4	8
40+	1	2	5	10	6	12

Table II: SYMPTOMS AND SIGNS

Symptom or sign	No. of cases	%
Nausea and vomiting	37	74
Abdominal pain	34	68
Diarrhoea	41	82
Bloody diarrhoea	37	74
Pyrexia above 38 °C	24	48
Shock	7	14
Clinical dehydration	35	70
Abdominal tenderness	40	80
Loss of bowel sounds	25	50

Table III: LABORATORY FINDINGS

Investigation	No. of cases	%
Haemoglobin <10 g per cent	6	12
Leucocytosis		
10 000–20 000/mm^3	26	52
>20 000/mm^3	12	24
Blood in stool*	44	100

* In 44 patients examined.

On examination a low grade fever was common. Twenty-four (48 per cent) of the patients had a temperature above 38 °C on admission. The highest temperature recorded on admission was 40 °C. Tachycardia was common (43 patients), but shock was found in only 7 patients. Clinically, many of the patients appeared dehydrated. A mild degree of abdominal distension was seen in half the patients. Abdominal tenderness was common (80 per cent of cases), but there was seldom any marked guarding or rigidity. Ascites was not detectable clinically. The bowel sounds were usually decreased, and in 50 per cent of the patients there was an absence of bowel sounds (*Table II*).

---

* Department of Surgery, Faculty of Medicine, University of Chiang Mai, Thailand.

Laboratory investigations

Six patients had a haemoglobin of less than 10 g per cent (*Table III*). Twenty-six had a leucocytosis of between 10 000 and 20 000/mm^3 and 12 had a leucocytosis above 20 000/mm^3. The neutrophil count was usually about 80 per cent, with a shift to the left. Platelet counts and estimations of prothrombin time in 3 patients were normal.

The faeces of 88 per cent of the patients were examined and all were found to contain blood. Parasites were found in 10 of 27 specimens of faeces examined. The parasites were hookworm, tapeworms, *Ascaris*, strongyloid larvae and *Opisthorchis* ova. Cultures were performed on 6 patients' faeces. One produced a growth of *Clostridium perfringens*. The others grew only normal gut commensals (none of these was an anaerobic culture).

Radiography

In the cases presenting early, anteroposterior upright and supine X-rays of the abdomen showed evidence of paralytic ileus with dilated loops of small bowel. In cases with a longer history short loops of small bowel were dilated and there was often thickening of the wall of the affected segments and an appearance of fixation. The distance between contiguous loops was widened. There was often evidence of free fluid in the abdominal cavity (*Fig.* 1). No barium studies were done.

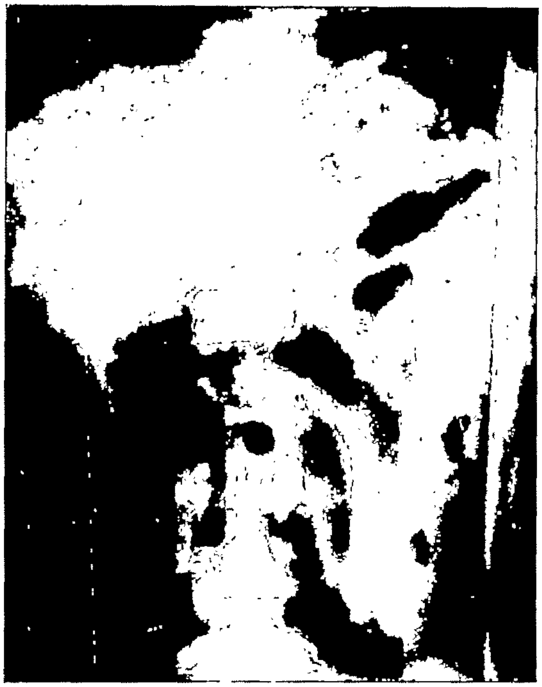

Fig. 1. X-ray showing dilated loops of small bowel and the presence of peritoneal fluid. There is thickening of the bowel wall.

Treatment and clinical course

All the patients in the series, except those who were diagnosed at autopsy as well as 6 others, underwent surgery. At laparotomy a length of small intestine showed ischaemic changes. In the early stages the bowel wall looked thickened and pale and there were often subserosal petechiae. In the later stages parts of the affected segment were deep red and friable. In 3 patients there were perforations of the affected bowel. In 29 patients (58 per cent) the segment was less than 100 cm long. The ischaemic segment was most commonly found in the jejunum (62 per cent). In 8 patients it was located in the ileum, and in 5 it affected both the jejunum and ileum. In 2 patients there appeared to be two affected segments separated by 15 cm of normal-looking intestine. In both these patients the lesions were in the lower jejunum and upper ileum. One patient was operated on for a perforated duodenal ulcer and the ischaemic segment of jejunum was found and resected. The duodenal ulcer was closed by simple suture. All the patients had enlarged mesenteric glands and free fluid, usually straw-coloured and odourless, in the peritoneal cavity. The mesenteric arteries were always found to be pulsatile and there was no evidence of arterial or venous thrombosis outside the bowel wall.

The patients not treated by surgical resection of the diseased intestine were all treated with tetracycline (250 mg 6-hourly) and hydrocortisone (100 mg 6-hourly) intravenously and intravenous fluids and nasogastric suction. They were allowed to take oral liquids and diet when the abdominal pain settled and they no longer had bloody diarrhoea.

Forty-three of the 50 patients survived. Of the 7 who died, 3 were diagnosed at autopsy. Another patient had prolonged postoperative diarrhoea and abdominal distension followed by dehiscence of the abdominal wound. A fifth had a gastrostomy done for dilatation of the stomach and this leaked, causing fatal complications. A sixth died from septicaemia and at autopsy was found to have miliary abscesses in the lungs. The remaining patient developed a faecal fistula and disrupted wound. The average duration of stay in hospital was 17 days.

It has been interesting to confirm Headington's observation (Headington et al., 1967) that the disease is most commonly seen during the rainy season (that is, between May and November). Only 3 patients were seen outside that time.

Pathological findings

In every case the ischaemic bowel was limited to the small intestine. No involvement of the duodenum, appendix or colon was seen. The area of transition between the normal bowel and the affected segment was not more than 3–4 cm wide and in most cases there was a distinct line of demarcation. The intestinal wall was thickened, producing relative narrowing of the lumen. The mucosa looked oedematous and haemorrhagic but no superficial ulceration was seen.

Microscopically, there was haemorrhagic necrosis and inflammatory oedema involving the mucous membrane, submucosa and muscularis mucosa. There was coagulative necrosis of the tips of the plicae. Thrombosis of the intramural vessels was commonly seen and in 2 cases an Arthus-like phenomenon was seen. The bowel wall was infiltrated with inflammatory cells—histiocytes, round cells and some polymorphonuclear leucocytes. The serosa contained a serous exudate with a few cells. Lymph glands showed hyperplasia with some haemorrhage into the glands, but no loss of nodal pattern. Gram stains failed to reveal a common pathogen. Associated parasites are described under laboratory investigations.

Discussion

Acute segmental ischaemic enteritis is an uncommon condition which mainly affects young people. It is characterized by an ischaemic length of small intestine. The ischaemic changes may be reversible. It is possible to make a confident preoperative diagnosis in most patients. The characteristic findings are abdominal pain associated with a mild fever and bloody diarrhoea.

In Pig-bel disease, which has been described in New Guinea (Murrell et al., 1966), lengths of ischaemic intestine have been found. A β-toxin-producing strain of *Clostridium perfringens* (*Clostridium welchii*) has been implicated (Egerton, 1966). The disease may be related to the ingestion of food which is infected or produces a localized allergic reaction. The vessels supplying the small intestine appear normal both macroscopically amd microscopically.

Acute segmental ischaemic enteritis as seen in Thailand has some features in common with Pig-bel disease. We feel that the disease in Thailand is a different disease from Pig-bel despite the fact that both are characterized by ischaemia and necrosis of lengths of small intestine. Both diseases are most commonly seen in children and young adults and are more frequent in males (Murrell, 1966). Pig-bel disease has often occurred in epidemics following pig feasts. The similar condition in Thailand has only been recognized in scattered, individual cases. The following features noted in Pig-bel disease have not been found in acute segmental ischaemic enteritis in Thailand: marked abdominal distension with a *very tender* abdomen, the presence of smelly, serosanguinous fluid in the peritoneal cavity, discoloured fibrinous exudate on the small bowel and an intensely haemorrhagic, swollen and oedematous mesentery (Roth, 1966). Residual multiple stenosis and short-circuited loops with resulting malnutrition and malabsorption have been described in Pig-bel disease. None of these features has been seen in any of the patients with acute segmental ischaemic enteritis.

The presence of parasites in the gastro-intestinal tract of patients affected by acute segmental ischaemic enteritis was not higher than the expected incidence in northern Thailand (Cunningham et al., 1970). There is no evidence to implicate parasites as an aetiological factor.

Acute segmental ischaemic enteritis closely resembles the condition described by Zeissler et al. (1949). They were able to identify a bacillus which they called '*Cl. welchii* type F' from specimens obtained from several patients with enteritis necroticans. They described colonies of this organism having smooth single rods with no flagella. Its spores showed high thermal resistance. The bacillus produced traces of *Cl. welchii* α-toxin and considerable quantities of β-toxin. Injections of a 1-day-old culture into guinea-pig intestine led to the development of enteritis necroticans, and they concluded that the damage to the intestine was due to the β-toxin of *Cl. welchii* type F. It is unfortunate that extensive bacteriological studies were not done on specimens obtained from our patients, for it seems very likely that the condition seen in Thailand and that described by Zeissler et al. are the same disease.

After Headington et al. (1967) diagnosed the first 2 cases of acute segmented ischaemic enteritis at autopsy, his next 3 patients were treated by resection of the affected segment of intestine and survived. In a patient whose case history is described above almost all the small intestine appeared ischaemic and no resection was performed. The abdomen was closed and postoperatively the patient made a good recovery. Six patients have since been successfully treated without resection of the ischaemic intestine. Another patient, a 24-year-old man, appeared to be doing well with steroids and broad spectrum antibiotic therapy. On the eighth day of treatment he was rather unwisely given a bowl of meat, vegetables and noodles, having previously only taken sips of water. Soon afterwards he developed severe abdominal pain and at laparotomy was found to have multiple perforations in a segment of ischaemic jejunum. Following resection of this length of jejunum he made a good recovery.

We feel that non-operative treatment is the treatment of choice for patients in the early stages of the disease. Six patients have now survived without resection of intestine. These patients were treated with broad spectrum antibiotics (usually tetracycline 250 mg 6-hourly intravenously) and hydrocortisone (100 mg 6-hourly intravenously). This treatment is empirical as the aetiology of the disease is unknown. Patients being treated in this way must be observed closely as they are liable to develop gangrene of the bowel wall and perhaps perforation. Conservative treatment may be best for patients in the early stages of the disease, but once gangrene is established and the viability of the bowel wall is seriously threatened, or if perforation occurs, surgery is necessary.

Although this disease is not common, it does offer a challenge for further investigation to discover its cause. Professor Black's suggestion (1966) that epidemiological and anthropological studies might shed light on the aetiology of Pig-bel disease might equally apply to acute segmental ischaemic enteritis.

Cause and management of high volume output salt-depleting ileostomy

G. L. HILL, W. S. J. MAIR AND J. C. GOLIGHER*

SUMMARY

Ileostomy function was studied in 12 patients with an established ileostomy following proctocolectomy, in 6 of whom minimal amounts (less than 9 cm) and in 6 significant amounts (30–120 cm, mean 60 cm) of terminal ileum had been removed.

Patients who had undergone significant ileal resection had daily faecal volumes considerably greater than those with minimal ileal resection (1202 ± 284 ml versus 401 ± 92 ml, $P < 0{\cdot}001$), and also greater daily outputs of sodium (146 ± 53 mEq versus 43 ± 12 mEq) and potassium (12·7 ± 9·0 mEq versus 4·0 ± 0·99 mEq). The percentage water content of the ileostomy fluid was greater in patients who had had the ileum resected (93·1 ± 1·8 per cent versus 89·8 ± 2·5 per cent). In addition, the sodium/potassium ratio in the urine in patients with a properly acting ileostomy after ileal resection was low.

It is concluded that when recurrent inflammatory bowel disease, partial small bowel obstruction and intraperitoneal sepsis have been excluded there remains a number of patients whose high ileostomy output is due entirely to the amount of ileum resected.

The management of patients with a high output ileostomy with codeine phosphate, Lomotil and oral administration of sodium chloride tablets is discussed.

THE majority of patients who have an ileostomy live an apparently normal life and appear unaffected by the chronic loss of water and sodium from their ileal fistula. However, the susceptibility of ileostomy patients to sodium depletion has been clearly demonstrated (Gallagher et al., 1962). Direct studies of body composition have shown deficits in both water and body salt (Clarke et al., 1967), and deficits occurring before surgery are not repaired once the ileostomy is established (Hill, Goligher et al., 1975). Particularly susceptible to water and salt depletion are patients in whom the ileostomy volume is abnormally large. After recurrent inflammatory bowel disease, partial intestinal obstruction and intraperitoneal sepsis have been excluded there remains a group of patients with a high volume salt-losing ileostomy in whom no particular cause for this complication can be found. This report describes the aetiology of the profuse ileostomy output in this type of patient and outlines how this problem may be managed.

Patients and methods

Twelve patients who had had an ileostomy for more than 6 months were studied. The clinical details of each patient are given in *Table I*, from which it will be seen that *Cases* 1–6 had had minimal ileal resection (4–9 cm), whilst *Cases* 7–12 had undergone significant excision of ileum (30–120 cm). At the time of the study all the patients were well and living active lives and none had had any alteration in ileostomy function over the preceding few months. There was no clinical evidence of recurrent disease or of ileostomy stenosis in any of the patients and none was taking any medication during the period of study.

All the patients were studied for 3 days in hospital. During this time they were on a normal diet apart from the fact that no additional salt was permitted with meals. Each 24 hours the total output of ileostomy and of urine was collected and recorded and the amounts of sodium and potassium in these fluids were determined. In the case of ileostomy fluid the electrolyte concentrations were measured on the supernatant of an aliquot of aqueous homogenate using an EEL Integrating Flame Photometer no. 227. The water content of the ileostomy fluid was determined by taking aliquots of known weight (A) and drying to constant weight (D). Then, from the total weight of the ileostomy fluid (F) and the weight (W) of distilled water added, the water content was calculated as follows:

$$\text{Water (per cent)} = 100\left(1 - \frac{D(F+W)}{FA}\right).$$

In addition, *Cases* 3, 10 and 11 were investigated in more detail over a 12-month period. Collections of ileostomy fluid and of urine were made on the first 11 postoperative days after the ileostomy was established. Similar collections were obtained at 1, 6 and 12 months after operation. At 12 months *Cases* 10 and 22 underwent a 12-day study in a metabolic ward. During the first 4 days of this period the patients were on a normal diet containing sufficient calories calculated to provide maintenance requirements appropriate to each patient's weight and activity. No additional salt was provided with the diet and care was taken to avoid prune juice, quantities of cooked cabbage, etc. —substances which are known to increase ileostomy output (Kramer et al., 1962). During the entire study period 24-hour collections of ileostomy fluid and of urine were made. At the end of the 4-day control period the patients were given codeine phosphate 45 mg by mouth every 6 hours for another 4 days. At the conclusion of the second 4-day collection period (on day 9), whilst continuing on the normal diet and codeine phosphate medication, oral sodium chloride was added in a dose of 2 g every 6 hours, and the codeine and salt were continued at these dosages until the end of the study on day 12. The results were statistically evaluated by calculating the mean values ± 1 s.d. and applying the non-paired *t*-test.

Findings

Volume of ileostomy output

Table I shows that *Cases* 1–6 had considerably smaller faecal volumes than *Cases* 7–12. The mean 24-hour faecal volume measured over the 3-day period was 401 ± 92 ml for *Cases* 1–6 (low volume group) compared with 1202 ± 284 ml ($P < 0{\cdot}001$) for *Cases* 7–12 (high volume group) (*Table II*). The mean age of the low volume group was 47·3 years (range 29–63 years) compared with 40·3 years (range 27–71 years) for the high volume group. The mean body weight of the low volume group was slightly less than that of the high volume group (56·8 ± 12·7 kg and 58·4 ± 10·0 kg respectively). Apart from a preponderance of males in the high volume group, the most striking attribute of these patients appears to be the fact that each had had an ileal resection (*Table I*).

Chemistry of ileal effluent

Table II compares the ileostomy chemistry in the low volume group with that of the high volume group. The water content in the low volume cases was significantly less than in the high volume cases. The concentration of sodium and potassium in the ileostomy fluid, however, was not significantly different between the two groups. The Na/K ratio in the ileostomy fluid was significantly lower in the low volume group. This difference was even more marked when *Case* 7 was excluded; he had a Na/K ratio in his ileostomy fluid of 2·8 and no sodium could be detected in his urine.

Changes in quantity and composition of ileostomy output on serial studies

Low volume output ileostomy: *Fig.* 1 illustrates the pattern of ileostomy function of *Case* 3, who was followed from the day his ileostomy was established for intervals up to 12 months. At no period was this patient on steroids. His ileostomy behaviour is typical

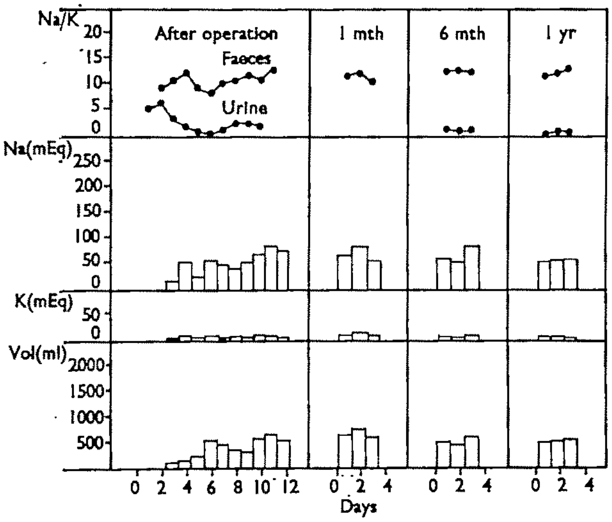

Fig. 1. Ileostomy chemistry in *Case* 3 measured at intervals over a 1-year period dating from the day of operation. Each vertical column in the histograms represents the output over a 24-hour period.

Results given as mean ±s.d.

of the low volume ileostomy, which we have described for a larger group of patients elsewhere (Hill, Mair and Goligher, 1975a). The faecal output, which was small at first, increased rapidly until the sixth postoperative day when a steady state was reached. The mean 24-hour faecal volume for days 7–12 after operation was 620 ± 44 ml and remained at 596 ± 67, 546 ± 67 and 530 ± 27 ml at 1, 6 and 12 months respectively. The daily faecal output of sodium and potassium similarly remained constant over the period of the study. There was, however, a marked fall in the water content of the ileostomy fluid between the first and second postoperative weeks (95·8 ± 2·9 per cent to 90·9 ± 0·63 per cent, $P < 0·005$). After 1 month the water content of the ileostomy fluid had fallen further (90·0 ± 0·63 per cent to 87·0 ± 58 per cent, $P < 0·001$), but thereafter there was no further significant change, with the percentage of water in the ileostomy fluid remaining between 87 and 89 per cent for up to 1 year. After the ileostomy volume had become stable the Na/K ratio in the fluid remained constant at around 12.

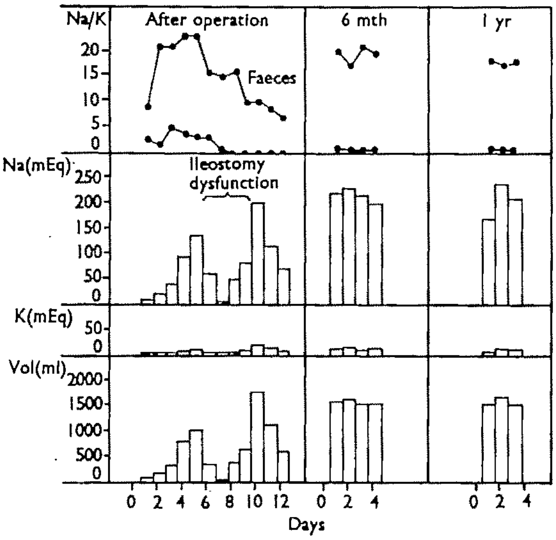

Fig. 2. Ileostomy chemistry in *Case* 10 measured at intervals over a 1-year period dating from the day of operation.

High volume output ileostomy: *Fig.* 2 describes the ileostomy function of *Case* 10 who was likewise followed from the immediate postoperative period at intervals for up to 1 year. At no time was he on steroid hormones. He provides a typical example of the ileostomy function found in a high volume type of ileostomy with an ileal resection (Hill, Mair and Goligher, 1975a). From the outset the faecal volume and output of sodium and potassium were higher than in the low volume ileostomy case. This higher output persisted over the 12-month study period (*Fig.* 2). The mean 24-hour faecal volume during the second postoperative week was 1011 ± 541 ml. At 6 and 12 months the daily faecal volume was 1590 ± 71 and 1543 ± 95 ml respectively. Although there was a significant fall in the water content of the ileostomy fluid between the first and second postoperative weeks (98·0 ± 0·6 per cent to 96·5 ± 22 per cent, $P < 0·025$), the water content did not fall further and remained around 95 per cent when measured at intervals up to 12 months.

The Na/K ratio in the ileostomy fluid was considerably higher than in the low volume group and was always above 15 apart from the second postoperative week when it fell concomitantly with the urine Na/K ratio, which was very low during this period.

Examination of *Fig.* 2 shows a marked reduction in volume and sodium output from days 6 to 9 in the postoperative period. During this time the patient had cramp-like abdominal pain and he provided a typical example of ileostomy dysfunction (Warren and McKittrick, 1951) from which he quickly and spontaneously recovered.

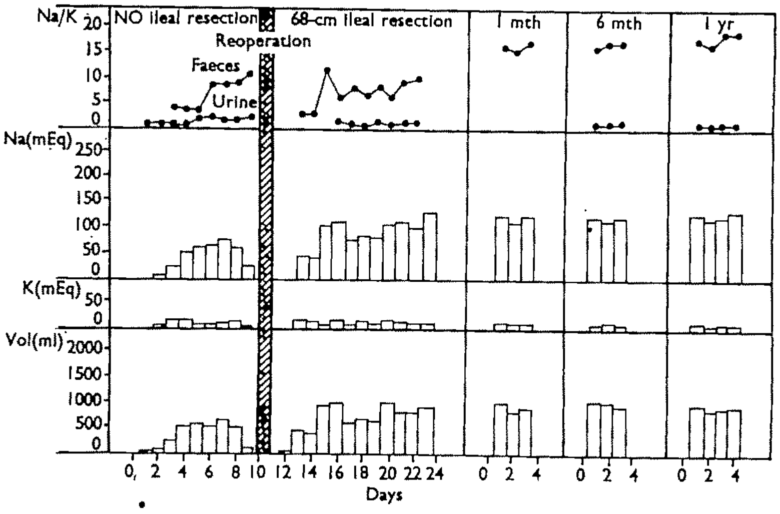

Fig. 3. Ileostomy chemistry in *Case* 11 measured at intervals over a 1-year period dating from the day the ileostomy was first established.

Low volume output ileostomy changing to high volume output ileostomy after secondary ileal resection: *Fig.* 3 describes the changes in ileostomy function in *Case* 11. He underwent proctocolectomy and ileostomy on 15 March 1973 for extensive ulcerative colitis. No ileal resection was performed at this operation and macroscopically and microscopically the ileal mucosa appeared normal. The operative period was covered by hydrocortisone administration 100 mg every 6 hours, and the dosage was then reduced rapidly until the eighth postoperative day when the dosage was 25 mg every 6 hours.

During the first postoperative week ileostomy function in this patient was typical for the low volume ileostomy. By the fourth postoperative day the 24-hour faecal volume was 530 ml and the daily volume remained within this range until the ninth postoperative day, when the patient developed severe abdominal pain and fever and the ileostomy ceased to function. On the tenth postoperative day lower abdominal tenderness developed and the perineal wound appeared tense and painful. The hydrocortisone dosage was returned to 100 mg every 6 hours and he was transferred to the operating room where laparotomy revealed that the ileum was caught up in the perineal wound and perforated in two areas, but there was no generalized intra-abdominal septic process. The terminal 68 cm of ileum, containing the perforated areas, were resected, the ileostomy was re-established in the right iliac fossa and the wound was closed. Subsequently the patient made an uninterrupted recovery and the hydrocortisone was reduced rapidly as after the primary operation and was discontinued by the end of the second postoperative week.

Following this second procedure in which 68 cm of terminal ileum were removed, ileostomy function assumed the character of a high volume ileostomy: On each postoperative day the ileostomy volume was larger than the corresponding day after the first procedure. The mean 24-hour faecal volume from days 4 to 8 after the first operation was 568 ± 52 ml, which was considerably smaller than the mean 24-hour faecal volume for the same period after the ileal resection (794 ± 178 ml, $P<0{\cdot}025$). At 1 month the daily faecal volume was 977 ± 126 ml, at 6 months it was 1033 ± 49 ml and it was 975 ± 76 ml at 1 year. At 1 year the water content (93 per cent) daily sodium output (130 mEq) and daily potassium output (7 mEq) were characteristic of a high volume ileostomy. The Na/K ratio remained consistently greater than 15 after the first month.

Effect of codeine and salt on the high volume ileostomy: *Table III* shows the effect of codeine phosphate alone and the effect of codeine phosphate and salt on ileostomy function in *Cases* 10 and 11. In both patients codeine phosphate caused a reduction in the daily faecal volume, which in one of them achieved statistically significant proportions. Addition of salt together with the codeine did not alter the faecal output. In both patients the water content of the ileostomy fluid fell and this reduction continued after the addition of salt.

In both patients there was a striking fall in ileostomy output of sodium and this persisted after the addition of salt. There was no change in the concentration of sodium in the ileostomy fluid in either patient during the study. Daily ileostomy excretion of potassium fell with codeine administration and this fall persisted after the administration of salt.

Fig. 4 illustrates these changes as seen in *Case* 10, and also shows the changes in the Na/K ratio in both the ileostomy fluid and the urine. *Case* 10 had been taking codeine phosphate tablets as an outpatient prior to admission to the metabolic ward for the study. *Fig.* 4 shows that the effect of this codeine was still apparent on day 1 of the study. The faecal volume was low, the faecal Na/K was low at 12·5 and he was in satisfactory sodium balance with a urine Na/K of 1·9. By the fourth control day (off all medication) his

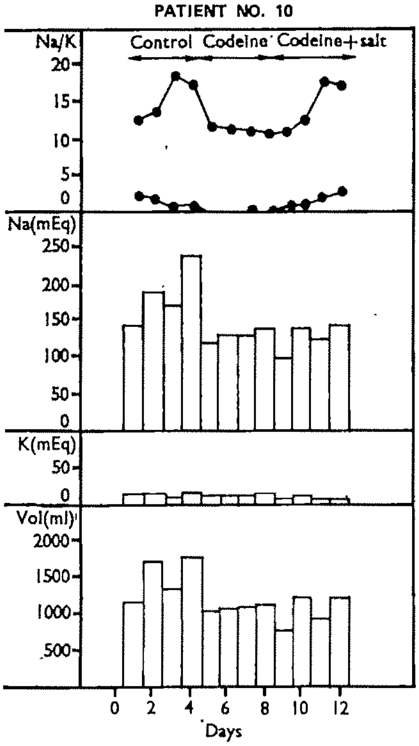

Fig. 4. Day-to-day changes in ileostomy chemistry in *Case* 10 during a control period, after the administration of codeine phosphate and after the administration of salt tablets together with codeine phosphate.

faecal volume had risen from 1150 ml on day 1 of the study to 1790 ml and the faecal Na/K ratio had risen from 12·5 to 17·5. Urinary conservation of sodium was now seen with a Na/K ratio of 0·09. On days 5 and 6 sodium disappeared from the urine.

After the administration of codeine phosphate the daily faecal volume fell within 24 hours to 1010 ml, and the consequent fall in sodium output from the ileostomy resulted in a reappearance of sodium in the urine, although the Na/K ratio remained low at 0·05.

After the administration of salt together with codeine phosphate the daily faecal volume remained low although the faecal Na/K rose, but this was due to a fall in potassium excretion rather than a rise in sodium excretion. Only after taking salt for 2 days did the urine Na/K ratio rise above 1, and by day 12 the Na/K ratio of 2·47 demonstrated good sodium balance.

Discussion

It is widely appreciated that if a significant amount of ileum is resected at the time of an ileostomy the output from the resulting ileostomy tends to be unusually profuse. A more accurate examination of the relationship between the amount of ileum resected and the amount of ileostomy output has been conducted by Nuguid et al. (1961). The present study affords still further precise confirmation of the role of ileal resection in increasing the amount of ileostomy effluent. This is shown in *Tables I* and *II* and in particular by *Fig.* 3, which demonstrates how in *Case* 11 a 'low volume ileostomy' was converted to a 'high volume ileostomy' after 68 cm of ileum were resected at a subsequent operation. Admittedly, it might be objected that the group of patients in our series with low output from their ileostomy was not strictly comparable with the group with high output, because in the latter there was a preponderance of males and the average age was less. There is, however, no strong evidence that men have on average higher output from their ileostomy than do women, and in the present study the tallest man (*Case* 6) had one of the lowest faecal outputs, whilst one of the smallest and oldest women (*Case* 12) had a large faecal volume.

How ileal resection results in a raised ileostomy is not fully understood. An obvious explanation is that it does so simply by loss of a significant amount of absorptive intestinal mucosa known to be important in the net transport of fluid and sodium (Hill, Mair and Goligher, 1975a), but since oral administration of bile salts increases the ileostomy output (Miettinen and Peltokallio, 1971) it is possible that the large volume of ileostomy effluent associated with ileal resection is a consequence of high bile salt concentration in the ileostomy fluid. Evidence that high concentrations of bile salts are present in some patients with an ileostomy has been provided by Miettinen and Peltokallio (1971), and there is nearly twice the incidence of gallstones in ileostomy patients who have had an ileal resection (Hill, Mair and Goligher, 1975b), suggesting an increased excretion of bile salts in such patients.

Many different drugs have been used to decrease ileostomy volume and sodium loss. Newton (1973) studied the effect of codeine phosphate, Lomotil and Isogel on ileostomy output of subjects living a normal life. It was concluded that codeine phosphate decreased the loss of sodium, potassium and water and that Lomotil had a similar but less pronounced action. Isogel, however, actually increased ileostomy volume and output of sodium and potassium. The present study confirms the beneficial effect of codeine phosphate, which effectively reduced ileostomy volume and sodium and potassium loss in 2 patients with a high volume ileostomy.

Sodium chloride given intravenously in the form of normal saline results in an increased volume of ileostomy output, but this response is not seen in patients who have had an ileal resection (Clarke and Hill, 1966; Hill, Mair and Goligher, 1975a). Orally administered sodium chloride also increases the volume of ileostomy effluent, but this effect is not marked until the total salt in the diet is 15 g or more a day (Kramer, 1966). It might be expected, therefore, that since the effect of oral and intravenous salt appears to be similar, patients with ileal resection might tolerate more oral salt without increased ileostomy output. Our clinical experience is consistent with this hypothesis, for in 2 patients when a daily dose of 8 g of sodium chloride was given orally over and above their usual dietary intake, there was no increased ileostomy output and the rise in the urine Na/K ratio showed a return to normal sodium balance.

Based on these studies and on clinical experience of a large number of other cases with a properly acting ileostomy, we have formulated a programme of management for patients who present with a high output ileostomy.

First of all, it should be pointed out that not every patient with an overactive ileostomy recognizes that he is different from other ileostomists. He may mention that he empties his ileostomy bag six or more times daily and has more than the usual trouble with leakage. There may be some complaint of occasional dizziness or light headedness from salt depletion or from excessive tiredness. If these manifestations are recent or associated with crampy abdominal pains, fever, weight loss or abdominal distension, the patient should be fully investigated for recurrent disease, intestinal obstruction or intra-abdominal sepsis.

After a thorough general physical examination the ileostomy is inspected and palpated with a finger for stricture. A specimen of ileostomy fluid and urine are sent to the laboratory for chemical analysis. A small bowel meal radiological study is then ordered and possibly an oral cholecystogram as well.

After recurrent disease, small bowel obstruction, intra-abdominal sepsis and chronic dietary indiscretion have all been excluded, there remains a group of patients in whom no specific cause for the high ileostomy output can be found. It is our experience that these patients have nearly always had an ileal resection. Characteristically, the ileostomy fluid appears watery and the Na/K ratio in the ileostomy fluid is greater than 15 whilst that in the urine is less than 1. Very rarely the patient with an ileal resection can have a faecal Na/K ratio of less than 5, but this is usually seen only in the early postoperative period or in very severe salt depletion (Clarke et al., 1967). In salt depletion of this magnitude sodium is absent from the urine. Although more elaborate and time-consuming 24-hour faecal and urine collections may be performed, we rely heavily in outpatient assessment on the simple measurement of the concentration and sodium and potassium in random specimens of ileostomy fluid and urine and on the calculation of the Na/K ratios. If the faecal Na/K ratio is below 15 and the urine Na/K ratio is greater than 1, the patient can be presumed to have satisfactory ileostomy function.

When the diagnosis of a high volume salt-losing ileostomy has been established, we commence the patient on 30–60 mg codeine phosphate every 6 hours and 2 g of salt every 6 hours. In 1 week's time he is seen again and questioned about his faecal output. Satisfactory reduction in volume is indicated by a reduction in the number of times he empties his bag (should be less than four to five times daily), and satisfactory sodium balance is indicated when the urine Na/K ratio rises above unity.

It is our experience that if the ileostomy overactivity is due entirely to ileal resection and is unassociated with any other abnormality it can usually be controlled by these means. If the codeine phosphate should cause side effects or prove ineffective, Lomotil is used as a substitute or supplement. It is not often necessary for the dose of codeine phosphate to be above 60 mg every 6 hours, but on occasion this becomes necessary and we do not hesitate to raise the dose considerably higher. Adequate control of the ileostomy volume with codeine phosphate rarely necessitates additional salt above 9 g/day, at which point the salt itself may result in an increased ileostomy output.

We wish to stress, however, that in the rare patients who do not respond to this regimen and whose ileostomy volume does not fall or falls only intermittently and in whom the urine Na/K remains less than 1 and the faecal Na/K is high (20 or more), the possibility that some pathological process of the small intestine may be causing the ileostomy dysfunction should be reconsidered and a full investigation undertaken. In some particularly difficult patients of this type we have exceptionally resorted to laparotomy as a further diagnostic step when all other investigations have proved unhelpful or inconclusive.

The pick of the bunch for skin disinfection

'Dispray' 1 Quick Prep.
(formerly known as Hibispray 1)
is an ideal preparation for skin and
hand disinfection in the busy
hospital environment.
At the touch of a button it gives
fast, easy and economical
skin disinfection prior to surgery,
injection or venepuncture.
When colour delineation
is required eg. pre-operatively,
'Dispray' 3 is available
with a red dye.

The 'Dispray' range
combines effectiveness with
convenience and economy.

Instant Availability.
No solutions to prepare.

Easy to use.
No swabs or bottles required.

Quick and Effective.
Rapid bactericidal action.

Efficient Application.
No wasted solutions.

Contents cannot
be contaminated.
No rejected solutions.

Long Lasting.
Contents of one can treat 100sq.ft.

Factors influencing local recurrence after abdominoperineal resection for cancer of the rectum and rectosigmoid

A. R. MOOSSA, P. C. REE, J. E. MARKS, B. LEVIN, C. E. PLATZ
AND D. B. SKINNER*

SUMMARY

One hundred and fifty-two patients who underwent abdominoperineal resection for cancer of the rectum and rectosigmoid are reviewed. Six physicians were selected to predict which of these patients would have a local recurrence. All the information available at the end of the operation was duplicated and submitted to the observers. None of the physicians was able to predict local recurrence significantly better than random. There were 31 local recurrences, i.e. an incidence of 20·4 per cent. Low level of tumour in the rectum, local spread into perirectal fat or serosa, lymph node involvement and age below 60 years at time of operation were the only factors that were statistically related to local recurrence. The strategy for careful follow-up of patients at risk is outlined and a plea is made for a controlled trial of postoperative radiotherapy.

LOCAL tumour recurrence after abdominoperineal resection for cancer of the rectum and rectosigmoid junction remains a difficult clinical problem. Some 10–20 per cent of the 37 000 new cases seen each year in the United States will develop local and/or regional node recurrence following surgical treatment. About 50 per cent of the patients with local failure do not have distant metastases and yet the quality and duration of their survival are adversely affected. Clearly, the ability to identify subgroups of individuals at high risk would be advantageous in the selection of patients for adjuvant therapy and in the planning of the postoperative follow-up régime.

We investigated the ability of the physician to predict which patient is going to have a local recurrence and also to elucidate the factors responsible for such local failure. The preliminary results on the first 74 patients studied have already been discussed (Ree et al., 1975).

Patients and methods

Between 1943 and 1972 at the Department of Surgery, University of Chicago, 152 patients underwent abdominoperineal resection for cancer of the rectum and rectosigmoid and survived the first 30 days after operation. They were all followed up until death or for a minimum of 2 years, so that the majority of recurrences could be detected. Six physicians were selected to predict which of these patients would have a local recurrence. There were two surgeons, two pathologists, one gastro-enterologist and one radiotherapist. All the information available at the end of the postoperative period was duplicated and each physician was given copies of reports on the proctoscopy, intravenous pyelogram, barium enema, operative report and surgical pathology report. They were asked to focus their attention on variables that might be related to local recurrence and to evaluate each patient according to six parameters—level of tumour in the rectum, histological grade of malignancy, Dukes' class, presence of tumour in resected margin, blood vessel invasion, lymphatic involvement. The observers worked independently of each other. The patient's actual outcome was recorded separately from the information in the charts and tumour registry records.

Table I: PREDICTION OF LOCAL RECURRENCE

	Observer					
	1	2	3	4	4	6
Cases predicted to have a local recurrence (% of total)	34	34	39	44	55	68
Local recurrence correctly predicted (%)	36	56	57	44	72	78

Table II: SITES OF LOCAL RECURRENCE

Site: Pelvis	No. of cases:	10
Perineum		13
Vagina		6
Abdominal wall		2
	Total	31

Results

None of the observers was able to predict local recurrence significantly better than random. The physicians who detected the largest number of recurrences also predicted the largest number (*Table I*).

From the charts we found that there were 31 local recurrences among the 152 patients, which is an incidence of 20·4 per cent. Thirteen were in the perineal region, 10 in the pelvis, 6 in the vagina and 2 in the anterior abdominal wall (*Table II*). The median time from operation to local recurrence was 8·5 months with a range of 2–89 months. Twenty-six of the 31 patients (84 per cent) presented with their local recurrence within 1 year of operation. The average survival after detection of recurrence was 15 months with a range of 2–51 months. Autopsy or

Table III: RELATIONSHIP OF LEVEL OF PRIMARY TUMOUR TO INCIDENCE OF LOCAL RECURRENCE

Level of primary tumour	No. of cases	Local recurrence No.	%
Upper third of rectum and rectosigmoid junction	28	1	3·6
Middle third of rectum	42	4	9·5
Lower third of rectum	82	26	31.7
Total	152	31	20·4

$\chi^2 = 11·46$, $P<0·005$.

Table IV: RELATIONSHIP BETWEEN LOCAL SPREAD OF TUMOUR AND INCIDENCE OF LOCAL RECURRENCE

Local spread into perirectal fat or serosa	No. of cases	Local recurrence No.	%
Yes	30	17	56·7
No	122	14	11·4
Total	152	31	20·4

$\chi^2 = 30·3$, $P<0·001$.

Table V: RELATIONSHIP BETWEEN REGIONAL LYMPH NODE INVOLVEMENT AND INCIDENCE OF LOCAL RECURRENCE

Regional lymph node involvement	No. of cases	Local recurrence No.	%
Positive	70	22	31·4
Negative	82	9	11·0
Total	152	31	20·4

$\chi^2 = 9·73$, $P<0·005$.

Table VI: RELATIONSHIP BETWEEN AGE OF PATIENT AND INCIDENCE OF LOCAL RECURRENCE

Age at time of operation (yr)	No. of cases	Local recurrence No.	%
<60	61	20	32·8
>60	91	11	12·1
Total	152	31	20·4

$\chi^2 = 9·638$, $P<0·005$.

Table VII: RELATIONSHIP BETWEEN MUCIN PRODUCTION AND INCIDENCE OF LOCAL RECURRENCE

Mucin production by tumour	No. of cases	Local recurrence No.	%
Positive	25	7	28
Negative	127	24	19
Total	152	31	20·4

$\chi^2 = 1·066$, $P<0·5$.

Table VIII: RELATIONSHIP BETWEEN SEX AND INCIDENCE OF LOCAL RECURRENCE

Patient's sex	No. of cases	Local recurrence No.	%
Female	81	20	24·7
Male	71	11	15·5
Total	152	31	20·4

$\chi^2 = 1·972$, $P<0·2$.

Table IX: RELATIONSHIP BETWEEN DUKES' CLASSIFICATION AND INCIDENCE OF LOCAL RECURRENCE

Dukes' class	No. of cases	Local recurrence No.	%
A	5	0	0
B	76	13	17·1
C	66	18	27·2
Not classified	5	—	—
Total	152	31	20·4

$\chi^2 = 1·964$, $P<0·2$.

Table X: RELATIONSHIP BETWEEN HISTOLOGICAL GRADE OF MALIGNANCY AND INCIDENCE OF LOCAL RECURRENCE

Histological grade	No. of cases	Local recurrence No.	%
Well differentiated	58	11	19·0
Moderately well differentiated	46	8	17·4
Poorly differentiated	15	3	20·0
Total	119	22	18·5

$\chi^2 = 0·05562$.

Table XI: RELATIONSHIP BETWEEN PERFORATION OF BOWEL WALL AND INCIDENCE OF LOCAL RECURRENCE

Perforation of bowel wall by tumour or surgeon	No. of cases	Local recurrence No.	%
Yes	25	5	20·0
No	127	26	20·4
Total	152	31	20·4

$\chi^2 = 0·0135$, $P = 0·995$.

Table XII: RELATIONSHIP BETWEEN VOLUME OF TUMOUR AND INCIDENCE OF LOCAL RECURRENCE

Volume of tumour in surgical specimen (ml)	No. of cases	Local recurrence No.	%
<10·0	45	9	20·0
>10·0	61	12	19·6
Total	106	21	19·8

$\chi^2 = 0·002$, $P>0·995$.

'second look' laparotomy data were available for 24 of the 31 patients. Only 13 of them had evidence of distant metastases.

The following factors were significantly related to local recurrence: low level of tumour in the rectum (*Table III*), local spread into perirectal fat or serosa (*Table IV*), lymph node involvement (*Table V*) and age below 60 years (*Table VI*). Mucin production by the tumour (*Table VII*), female sex (*Table VIII*) and Dukes' class (*Table IX*) showed a trend to local recurrence, but were not significantly related to it.

The following factors were unrelated to local recurrence: histological grade of malignancy (*Table X*), perforation of bowel by tumour or surgeon (*Table XI*), volume of tumour (*Table XII*) and the range of years when the operation was performed (*Fig.* 1).

Discussion

Over the past 30 years emphasis has been placed on earlier diagnosis of colorectal cancer. In spite of the intensive public education programmes and thorough investigations using endoscopy and cytological and radiological techniques, the relative incidence of the different stages of the disease has remained unaltered. The survival rates have improved but slightly. Most of the benefit can be accounted for by an increase in resectability rate with a lower operative mortality. The results of a 'curative resection' for each stage of the disease have remained virtually unchanged (Polk et al., 1973).

Opinions vary on the exact cause of mortality and morbidity following abdominoperineal resection for rectosigmoid cancer. Dionne (1965) believed that nearly all patients with colorectal carcinoma die as a result of venous spread of the disease. Our limited data do not support this contention. The majority of our patients with recurrent colorectal cancer died from local problems. This is borne out by the study of Floyd et al. (1965), who found that local tumour spread was the major cause of death in 25 of their 34 patients. The extensive post-mortem examinations carried out by Taylor (1962) demonstrated that in 75 per cent of his 125 patients death was due to local persistence of the growth.

The implications of our study support the view of others (Gunderson and Sosin, 1974) that the use of radical surgery as has been practised over the past 10 years does not necessarily prevent problems with local failure. The majority of recurrences occur within the first year after surgery, and this suggests that they are derived from microscopic or subclinical 'residual' tumour left during 'curative' operative attempts. Further, the high percentage of local recurrence in our group of patients cannot be attributed to the use of sphincter-saving procedures.

Our data show some unexpected trends which may be partially due to the small number of patients in our series. We have not confirmed the report of Morson et al. (1963) that the degree of histological differentiation is a prognostic factor for local recurrence. The higher incidence of local failure in women may be explained by the tendency of our surgeons to preserve the vagina. The biologically more aggressive rectosigmoid tumours in the young cannot be accounted for on the available data. We have not looked at other potentially important parameters such as germinal centre activity and sinus histiocytosis in lymph nodes and the presence of local wound sepsis.

The incidence and pattern of 'residual' or 'recurrent' cancer after abdominoperineal resection can be predicted fairly accurately if the basic anatomy of the rectum and pelvis, the pathologic extent of the primary lesion and the limitations of surgical technique are kept in mind. We believe that patients under the age of 60 years belonging to Dukes' classes B_2, C_1 and C_2 (Astler–Coller modification, 1954) who had the primary lesion at or below the peritoneal reflection should be included in a prospective random study of postoperative irradiation. The eligible patients in such a trial should be protected from unnecessary irradiation. The upper extent of the field should be based on the type of operative procedure and the degree of tumour involvement. Probably patients with local tumour spread should only receive irradiation to the lesser pelvis, while those with nodal metastases should receive additional treatment to the aorto-iliac and hypogastric nodal basins.

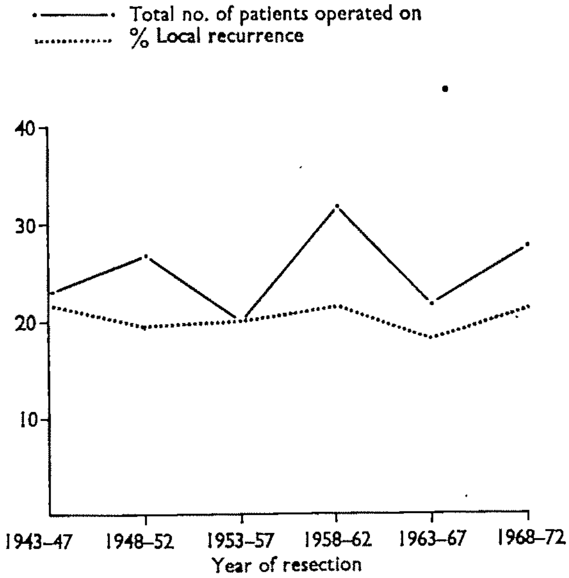

Fig. 1. Relationship between range of years when the operation was performed and incidence of local recurrence.

The strategy for postoperative follow-up of the patients at risk should be stringent during the first postoperative year (Ree et al., 1975). Careful perineal and vaginal examination is mandatory. Any residual sinus tract in the perineum should be probed and curetted and the material sent for histological diagnosis. The curative benefit of routine 'second look' laparotomy is dubious (Gunderson and Sosin, 1974). However, patients with suggestive symptoms, especially perineal or sacral pain, should be carefully evaluated and re-explored with a view to locating residual tumour early and excising the bulk of the recurrence. They could then be randomized in some adjuvant therapy protocol. The role of serial determinations of the carcino-embryonic antigen in selecting patients for reoperation is being currently investigated at our institution.

We have demonstrated that physicians are not always able to predict cases of rectosigmoid carcinoma in which local recurrence will appear following surgery. This does not imply that a *laissez-faire* attitude should prevail. The general pessimistic outlook regarding recurrent colorectal cancer is unjustifiable and the exact extent of these recurrences should be fully assessed (Polk and Spratt, 1971). Adjuvant therapy should be studied in detail to draw conclusions regarding improved tumour control and the complications of retreatment.

The transdiaphragmatic approach to the heart

E. W. J. CAMERON*

SUMMARY

A modification of the transdiaphragmatic approach to the heart is described. The technique has been used successfully in both adults and children, the youngest child being 8 years of age. The approach has advantages over others in gaining access to the heart for purposes of internal cardiac massage and drainage of suppurative pericarditis and is also a suitable manœuvre in the surgical treatment of acute tamponade. Clinical experience in the use of this approach is summarized. The transdiaphragmatic approach is recommended as a standard technique for internal cardiac massage.

THE transdiaphragmatic approach to the heart was first advocated by Sauerbruch (Siddons, 1968), who used a transverse epigastric incision. Modern descriptions of the approach are remarkable for their rarity. In instances where acute tamponade occurs after a cardiac operation performed through a median sternotomy it is common practice to open first the inferior end of the incision, since this limited exposure often serves to evacuate the blood without having to separate the sternal fragments. Most other descriptions advise entry at the left xiphocostal angle through the rectus sheath (Belsey, 1968; Ebert, 1969; d'Abreu et al., 1971). This approach is complicated by the close relation of the superior epigastric vessels and the risk to the marginal artery which underlies the natural point of entry into the pericardium. An approach through the linea alba and peritoneal cavity has also been described (McNair, 1972). Here the left lobe of the liver must be freed by division of the left triangular ligament. There is also the problem of coping with the abdominal contents. Fitzgerald (1966) has evolved a transdiaphragmatic approach through a left subcostal incision. Again, the greater sophistication of the anatomy makes this route less favourable than that now to be described.

Technique

A vertical skin incision is made in the midline; the centre point of the incision is the tip of the xiphoid process. Superiorly the incision is carried anterior to the sternum and inferiorly to midway between the tip of the xiphoid process and the umbilicus. The incision is deepened to the sternal periosteum and through the linea alba to the peritoneum. The xiphoid process is bisected vertically after its deep surface has been cleared with a finger or a dissector. By a combination of blunt dissection and lateral retraction of the wound edges the peritoneum is separated from the abdominal surface of the central tendon of the diaphragm, and the central tendon is displayed. The tendon is then grasped with tissue forceps, lifted with the parietal pericardium from the surface of the heart and incised through to open the pericardial space. The diaphragmatic pericardium is firmly adherent to the central tendon and the two structures can be incised without preliminary elevation to allow quicker and equally safe entry to the pericardial space. The primary incision is widened to display the diaphragmatic and anterior surfaces of the heart.

Discussion

This modification of the transdiaphragmatic approach has the particular advantages that it is rapid and simple to perform, that no vessels, nerves or muscles are divided and that there is no need to open the pleural or peritoneal cavities. It is the inferior end of the incision for mid-sternal thoracotomy and can therefore be extended superiorly to give a general exposure of the heart. The only necessary instrument is a scalpel. For cardiac massage the hand and wrist of the operator lie in a comfortable position, the extended fingers of the right hand over the lateral aspect of the left ventricle, the thenar eminence and thumb over the right ventricle. This contrasts with the thoracic exposure through which, without a self-retaining retractor, cardiac massage is difficult and even painful for the operator. Access for internal electrical defibrillation is easy by the abdominal route. Also, a single operator can simultaneously massage the heart and ventilate the lungs by mouth-to-mouth or tube technique.

The main theoretical danger with this approach is that when the pericardium is opened either the myocardium or coronary vessels may be injured. Myocardial injury should be repairable. The threatened coronary vessels, the marginal and right coronary arteries and their accompanying veins, should be avoided by siting the primary incision in the central tendon to the right of the midline over the diaphragmatic surface of the heart. Injury to the inferior vena cava could be produced by an unnecessary posterior extension of the incision. The chance of any such injury is minimal, particularly when the heart is still. When the parietal and visceral layers of the pericardium are mutually adherent, urgent intrapericardial manipulation of the heart is in any event impossible and the chance of cardiac injury on incision of the central tendon increases—a difficulty common to both the abdominal and thoracic approaches. It is, however,

Present address: Department of Anatomy, University of Edinburgh.

easier to perform effective extrapericardial massage by the abdominal than by the thoracic route. Obliteration of the pleural space may present an obstacle to access by the thoracic route. The abdominal route which does not traverse a serous cavity avoids this.

The most widespread use of the transdiaphragmatic approach would be for internal cardiac massage (ICM). This manœuvre has been eclipsed by the success and simplicity of external cardiac massage (ECM). The theoretical and experimental evidence of the superiority of ICM over ECM in terms of cardiac output has been summarized by Stephenson (1969). Weale and Rothwell-Jackson (1962), in experiments on dogs, have also demonstrated venous systolic pulses of up to 60 mm Hg on ECM. This poses a threat of brain damage which does not occur with ICM. Visceral damage caused to patients, particularly the elderly, by ECM is well documented. There are reports of instances where cardiac standstill despite ECM has been converted to action by subsequent ICM (Paul, 1964). It is still widely taught that failure to resuscitate by ECM is an indication for ICM, and it is certain that evidence of inadequate perfusion by ECM, for example dilating pupils where ventilation is satisfactory, is an indication for ICM. There are well-recognized groups of patients which are unsuitable for ECM, particularly those suffering from cardiac tamponade or stove-in chest, after pneumonectomy or women in late pregnancy. A single operator cannot manage resuscitation where he has simultaneously to ventilate the patient and perform adequate ECM.

The transdiaphragmatic approach has been used in the management of 5 cases of cardiac arrest. In 2 of these resuscitation was successful, in 2 unsuccessful and in 1 cardiac action was restored following ICM but subsequently rearrested. No technical problems were encountered in carrying out the transdiaphragmatic procedure.

Case reports

Case 1: A 52-year-old man sustained bilateral pulmonary contusion and multiple rib fractures in a car accident. He was treated with intermittent positive pressure respiration and during this procedure the endotracheal tube blocked and the patient had a cardiac arrest. In view of the chest wall injuries, resuscitation was managed by ICM. The patient subsequently recovered.

Case 2: A 26-year-old man had a Starr-Edwards replacement of an aortic valve 14 days before the sudden onset of ventricular fibrillation. Potassium levels were normal. External defibrillation failed. Sinus rhythm returned after internal defibrillation, and the patient subsequently recovered. A fault in the lead of one of the external defibrillator paddles was later discovered.

Case 3: A 68-year-old man had a cardiac arrest 60 minutes after the development of an anterolateral myocardial infarction. He was kyphotic. ECM caused bilateral rib fractures. The heart was in asystole prior to attempting ICM, which in turn proved futile.

Case 4: A 43-year-old man sustained an anterolateral myocardial infarction. Three hours after the onset of chest pain and after multiple ventricular extrasystoles, ventricular fibrillation occurred, followed by asystole. There was no sign of cardiac recovery after 30 minutes' ECM during which the heart was needled on several occasions. ICM was equally ineffective. There was a haemopericardium containing an estimated 50 ml of blood consequent on earlier cardiac puncture.

Case 5: A 60-year-old woman, admitted with a posterior myocardial infarction 4 days previously, had a cardiac arrest. She was 1·6 m tall and weighed 72 kg. Perfusion was inadequate on ECM. Six minutes after starting ICM there was satisfactory cardiac action. Subsequently, the patient had multiple arrhythmias and the heart went into asystole 3 hours after the initial resuscitation. All further attempts at resuscitation, including ICM, failed.

Drainage of suppurative pericarditis by this route is simple and effective. It allows of dependent drainage, no tissue compartment is breached in gaining access to the pericardium and the whole of the pericardium can be easily reached. This method has been used in the management of 4 cases of staphylococcal pericarditis. The patients were children aged between 8 and 12 years. All presented with pyopericardium and tamponade after failure of medical management to control the infection. In 2 children pyopericardium recurred after initial drainage through a left anterior thoracotomy with resection of the sixth or seventh costal cartilages. These patients were then redrained using the transdiaphragmatic route. All 4 patients recovered after transdiaphragmatic drainage.

The use of the approach for the relief of acute tamponade after cardiac operations has been mentioned. It is an equally reasonable method for the relief of traumatic tamponade where there is clinical and radiological evidence of only cardiac injury. Two patients, men of 20 and 22 years of age, presented with precordial stab wounds and clinical evidence of cardiac tamponade, and the chest X-rays showed globular enlargement of the pericardium. The transdiaphragmatic entry into the pericardium rapidly relieved the cardiac embarrassment. The surgical incision was then extended superiorly to complete a midsternal thoracotomy, and wounds in the left ventricular myocardium and great cardiac vein respectively were sutured. Both patients subsequently recovered.

Siddons (1968) has described the use of a transdiaphragmatic approach through the anterior rectus sheath to implant the epicardial loop of a pacemaker system.

The transdiaphragmatic approach is valid for the relief of acute cardiac tamponade and has advantages over the intercostal route for ICM and drainage of suppurative pericarditis. ICM may be an under-used resuscitatory technique, in which case simplification and standardization of the surgical approach to the heart would encourage the appropriate use of ICM. The proposed modification of the transdiaphragmatic approach is therefore the surgical approach recommended for ICM.

False abdominal aortic and iliac aneurysms

DEMETRIOS CHAVATZAS AND CRAWFORD JAMIESON*

SUMMARY

A case of late postoperative false abdominal aortic and iliac aneurysms complicated by malposition of the inferior vena cava is presented and attention is drawn to its presentation, diagnosis and management. Several factors assumed to be responsible for the formation of the false aneurysms 7 years after the previous grafting operation are discussed.

MAJOR aortic surgery began with the first resection of a saccular aneurysm of the aorta by Oschner in 1944 (Cooley and DeBakey, 1952), and in 1949 Swan et al. (1950) successfully excised a coarctation of the aorta with an associated aneurysm and replaced it with a homograft. Following the work of Voorhees et al. (1952), DeBakey et al. (1958), Martin (1963) and others, replacement of the human aorta by synthetic grafts has become standard practice, but problems still remain. We present a case of recurrent abdominal aortic and iliac aneurysms associated with malposition of the inferior vena cava, with emphasis on its presentation, diagnosis and management.

Case report

A 65-year-old man was admitted to Hammersmith Hospital complaining of a painful pulsatile mass in the lower abdomen over a period of 1 year. He also suffered from attacks of angina pectoris. Seven years previously abdominal aortic and bilateral iliac aneurysms had been resected with insertion of a Dacron bifurcation graft from 3 cm below the renal arteries to both external iliac arteries. A cholecystectomy for cholelithiasis had been performed at the same time. During the operation it had been noted that the inferior vena cava crossed from left to right anterior to the aneurysm. The patient had also had a myocardial infarction 8 years previously.

On general examination he was reasonably fit for his age, although obese, and his blood pressure was 180/100 mm Hg. Abdominal examination revealed a large tender pulsatile mass in the lower abdomen. The lower limb pulses were present and ultrasound studies showed ankle pressures of 130 mm Hg. Apart from slight ischaemic changes in the ECG, other routine investigations including haemoglobin, platelets, cholesterol, triglycerides and chest X-ray were normal. An arteriogram via a right femoral arteriotomy showed an aneurysmal right iliac artery poorly communicating with the lower abdominal aorta. The rest of the proximal and distal arterial tree was not visualized.

Via a wide transverse incision the peritoneal cavity was opened, and after a dissection made difficult by extensive fibrosis from the previous operation, a diffuse aneurysm of the right aorto-iliac region was seen (*Fig.* 1). Another large aneurysm with the sigmoid colon stretched over its surface filled the pelvis. The inferior vena cava crossed from left to right anterior to the aneurysm, and lateral to this a segment of the ileum was adherent to the wall of the aortic aneurysm. The aneurysm had eroded the ileal wall and rupture into the gut appeared imminent.

The inferior vena cava was divided and sutured just distal to the left renal vein in order to facilitate clamping and control of the neck of the aortic aneurysm (*Fig.* 2). The external iliac arteries were clamped and the aorta was clamped just distal to the renal arteries. After incision and evacuation of the aortic aneurysm the previously inserted graft (*Fig.* 3) was found to be loose and coiled in the pelvis; its proximal end was 15 cm from the point at which it had been sutured to the aorta. The prosthesis was removed. The segment of ileum attached to the wall of the aneurysm was freed together with a patch of thin aneurysmal wall. A new bifurcation graft was inserted from 1 cm below the renal arteries to the distal external iliac arteries (*Fig.* 4). The external iliac arteries were then ligated proximal to this graft. Since the pulse did not return in the pelvic aneurysm after flow was restored, both internal iliac arteries must have been thrombosed. The abdominal wound was closed in layers. Postoperatively, the patient suffered from reversible acute tubular necrosis and, as was expected, from bilateral leg oedema. Eventually, he recovered and was discharged home.

Discussion

It is known (Shatz et al., 1962) that in the presence of ischaemic heart disease, the patient is at risk of death from myocardial infarction as well as from rupture of his aneurysm, but our patient, though he suffered from angina pectoris, was clearly more at risk from rupture of the aneurysm into the ileum. This man, who was in his seventh decade with a history of myocardial infarction and aorto-iliac aneurysmectomies and suffering from ischaemic heart disease, responded satisfactorily to further abdominal and iliac aneurysmectomies 7 years after the first operation. This type of massive and multiple false aneurysm has not apparently been described in the British or American literature. More such cases will undoubtedly be seen in the future. Gastro-intestinal haemorrhage due to erosion into the gut, most commonly the duodenum, is now well documented (Shiel et al., 1969; Eastcott, 1973).

The cause of recurrent aneurysms and false aneurysms following arterial reconstruction for occlusive disease is not yet fully established. Sepsis may obviously contribute, but the great majority present late and in our and others' experience are sterile on bacterial culture. They are commonest in the femoral region, and the stress applied to the anastomosis of prosthesis to artery by movement of the hip joint has been advocated as a major cause (Stoney et al., 1965; Sawyers et al., 1967; Spratt et al., 1967). For this reason many surgeons attempt to avoid siting an anastomosis in the femoral artery. The reasons for this must be good, however, for a more proximal anastomosis is more difficult and also leaves a common site of recurrent stenosis in the common femoral artery distal to the reconstruction.

Much evidence has accumulated to incriminate silk sutures as a major cause of false aneurysm. Dacron

or Teflon never 'heals' satisfactorily to an artery and the integrity of the anastomosis probably depends indefinitely on its sutures. Silk loses its strength completely after a few years *in vivo* (Cutler and Dunphy, 1941), and most false aneurysms have been associated with its use (Moore and Hall, 1970). It is probable, therefore, that the employment of stronger synthetic suture materials will reduce the incidence of false aneurysms. There is also now a tendency for vascular surgeons to use heavier suture material, particularly for large diameter vessels. One must remember that the tension in a vessel wall is proportional to the product of its radius and the pressure within, so it is much higher in the aorta than in the popliteal artery although the blood pressure is almost identical. Silk sutures had been used in the original operation performed on our patient and had parted.

It seems that failure of the arterial wall itself, although believed to be of importance by some authors (Stoney et al., 1965), is a relatively uncommon cause of aneurysm, and aneurysm is rare following endarterectomy compared with its incidence after prosthetic replacement.

In conclusion the current available literature would suggest that the type and strength of suture used and the strict avoidance of sepsis are the most important factors in avoiding this complication of reconstructive arterial surgery.

Gastric acid secretion following renal transplantation

S. F. CANAVAN, J. D. BRIGGS AND P. R. F. BELL*

SUMMARY

Gastric acid secretion studies were performed in 10 patients on regular dialysis and again following transplantation. While on dialysis, the acid output was high, with mean peak values after pentagastrin of 37·2 mEq/h in males and 26·3 mEq/h in females. These compared with values in normal subjects of 21·6 mEq/h in males and 12·3 mEq/h in females.

Following transplantation continuous steroid therapy was given. Repeat gastric acid secretion studies showed no significant change, with values of 37·1 mEq/h in males and 24·6 mEq/h in females. The high incidence of gastro-intestinal haemorrhage and perforation following transplantation is probably due mainly to steroid therapy, but the ulcerogenic effect of steroids would not seem to be mediated by increased gastric acid secretion.

Introduction

This study was prompted by the high incidence of peptic ulceration following renal transplant surgery. Duodenal ulceration or multiple gastric erosions associated with a high mortality are particularly common (Penn et al., 1968; Moore and Hulme, 1969; Hadjiyannakis et al., 1971).

We have investigated the possibility that these patients are prone to peptic ulcer disease following transplantation because of hypersecretion of gastric acid. The basis for this rests on two facts: first, that steroids are known to increase the parietal cell mass with an increase in acid secretion in experimental animals (Clarke et al., 1960; Cooke and Grossman, 1966), and secondly, that patients on regular dialysis therapy have been shown to have a high acid output (Gordon et al., 1972; Ventkateswaran et al., 1972; Shepherd et al., 1973) and are prone to develop peptic ulceration (McLeod et al., 1966; Pendras and Erickson, 1966; Goldstein et al., 1967; Ventkateswaran et al., 1972; Shepherd et al., 1973).

It is possible that steroid therapy might further increase acid secretion and the susceptibility to peptic ulceration. Hence the present study was undertaken to examine the effect of immunosuppressive therapy on gastric acid secretion after transplantation.

Patients and methods

Between May 1969 and December 1973, 79 renal transplants were carried out in a total of 71 patients. There were 42 males and 29 females with a mean age of 36 years (range 16–47 years). Five of the kidneys were obtained from living donors, and the remaining 74 from cadavers. Before transplantation all the patients were maintained on twice- or thrice-weekly haemodialysis with a total of 20–24 hours per week.

Following transplantation prednisolone was given in a decreasing dose of 200 mg on day 1 to 40 mg on day 17, with a slower reduction thereafter to 15 mg at 3 months. Prednisolone 1 g was given intravenously at the time of transplantation and was repeated up to a maximum of 6–8 g during rejection episodes. Azathioprine was given as a single daily dose which ranged from 25 to 200 mg. The dose was adjusted to maintain the total white blood cell count between 5000 and 8000/mm^3. All the patients were given aluminium hydroxide (Aludrox) in a dosage of 30 ml 4-hourly for the first month after transplantation. Thereafter Aludrox was usually only taken as required for the relief of dyspepsia.

While on haemodialysis 10 patients (5 males and 5 females) were selected at random for gastric acid studies. Eight of these 10 patients also had barium meals performed (4 before and 4 after transplantation), and all were questioned for dyspeptic symptoms. The gastric acid studies were repeated, usually at about 3 months after transplantation. Nine of the 10 patients had functioning kidneys at this time.

The technique used was that of Johnston and Jepson (1967), and normal values for comparison were taken from the work of Baron (1963). Following an overnight fast a nasogastric tube was passed and residual gastric contents aspirated. Thereafter a collection of basal gastric secretion was obtained for the next two 15-minute periods. After the basal collection, pentagastrin 6 μg/kg body weight was given by intramuscular injection. Gastric juice was then aspirated for the next four 15-minute periods. Continuous mechanical aspiration was used throughout, augmented by manual aspiration and/or repositioning of the tube if drainage was not satisfactory and continuous at any time. The acid output was calculated after titration of an aliquot to neutrality with N10 sodium hydroxide using phenol red as an indicator. The peak output was defined as twice the maximum value of acid output during any two consecutive 15-minute periods.

Results

Details of the 10 patients who had gastric acid secretion studies are given in *Table I.* These patients were representative of the whole group in terms of age and sex. Barium meal studies showed a duodenal ulcer in only 1 of the 8 patients examined. Four of the

10 patients had dyspepsia before transplantation and a further patient developed dyspepsia following his transplant. *Table II* shows the results of the gastric acid secretion studies with normal values for comparison and significance levels.

In males the mean basal acid output was 3·8 mEq/h before and 3·4 mEq/h after transplantation. Both values were significantly greater than those in normal subjects. In females the corresponding figures were 1·2 mEq/h and 1·4 mEq/h, and they did not differ significantly from those in normal subjects. In the pre-transplant studies, the mean peak acid output following pentagastrin was 37·2 mEq/h in males and 26·3 mEq/h in females. Following transplantation there was no significant change in peak acid output, the mean values being 37·1 mEq/h in males and 24·6 mEq/h in females. Maximal acid concentration was slightly higher both in males (116 mEq/l) and females (104 mEq/l) while on regular dialysis than in normal subjects and did not change significantly after transplantation (males 122 mEq/l, females 94 mEq/l).

Five of the 71 patients had an episode of gastrointestinal bleeding due to peptic ulceration and one had a perforation. Four of those who bled and the patient whose ulcer perforated recovered following surgery but the remaining one died of uncontrollable bleeding. The incidence of haemorrhage from peptic ulcer was 7 per cent. Unfortunately, none of these patients was amongst those selected at random for acid secretion studies.

Discussion

Haemorrhage and perforation due to peptic ulceration are two of the more dangerous complications of renal transplantation and carry a high mortality. The combined incidence of these complications was found by

Penn et al. (1968) to be 5 per cent and by Hadjiyannakis et al. (1971) to be 11 per cent, with a mortality rate of 50 and 60 per cent respectively.

Although debate continues as to the cause of duodenal ulceration, there is general agreement that increased gastric acid secretion plays some part. Most previous reports have shown increased acid secretion in patients on regular haemodialysis (Gordon et al., 1972; Ventkateswaran et al., 1972; Shepherd et al., 1973), with higher than normal values following pentagastrin administration (Ventkateswaran et al., 1972; Shepherd et al., 1973), although Gordon et al. (1972) could confirm this only for female dialysis patients. In the present study basal acid output was high in males while on regular dialysis, but in both sexes the administration of pentagastrin produced high peak acid outputs. These findings are similar to those of Ventkateswaran et al. (1972) and Shepherd et al. (1973). It is of interest that in non-dialysed patients with chronic renal failure a similar incidence of hypersecretion has not been found (Ventkateswaran et al., 1972). In addition to these findings of high gastric acid secretion, there are numerous reports of an increase in the incidence of peptic ulceration in regular dialysis patients (McLeod et al., 1966; Pendras and Erickson, 1966; Goldstein et al., 1967; Ventkateswaran et al., 1972; Shepherd et al., 1973). Thus, patients presenting for transplantation are already a high-risk group.

It is widely believed that the very high incidence of peptic ulceration following transplantation is due mainly to steroid therapy. The results of this study have shown that no further increase in acid output occurs following transplantation in spite of a high intake of steroids. This suggests that steroids may not exert their ulcerogenic effect through the medium of increased acid secretion. Only one of the patients tested developed peptic ulceration but 3 patients had dyspepsia. In addition, none of the patients who suffered from bleeding or perforation had acid secretion studies performed, mainly because these complications occurred early in their postoperative course.

Other ways in which steroid therapy may contribute to the problem of peptic ulcer are by masking symptoms and signs (Beck et al., 1950; Sautter and Ziffren, 1959), causing deterioration in connective tissue (Creditor et al., 1950), and decreasing the production of gastric mucus (Menguy and Masters, 1963; Desbaillets and Menguy, 1967). Other factors which could contribute to peptic ulceration in the transplanted patient are stress, both physical and emotional, and hyperparathyroidism with hypercalcaemia (Barreras and Donaldson, 1967). Hypercalcaemia does not, however, occur commonly enough to be an important factor.

In view of the high mortality from peptic ulcer complications following transplantation, prophylaxis and effective treatment are important. Antacid therapy can be used in an attempt to prevent ulcer formation, but this practice is not without its drawbacks. Phosphate binding gels may cause hypophosphataemia and osteomalacia (Lotz et al., 1968). Magnesium intoxication can occur if magnesium salts are given to the patient with poor renal function (Hirschfelder, 1934; Alfrey et al., 1970), and hypercalcaemia may follow the use of calcium salts (Stiel et al., 1967; Malone and Horn, 1971). In addition, unless antacids are used almost continuously, they cannot produce an effective and lasting reduction in gastric acidity. As combined steroid and antacid therapy may mask symptoms and thus delay recognition of the presence of peptic ulceration, a more rational approach might be to give antacids only if dyspepsia develops.

More important than antacid therapy is the recognition and treatment of peptic ulcer, if this is present, prior to transplantation. It is now the policy in our unit to carry out barium meal examinations routinely and in some cases gastroscopy as well in potential transplant patients. If a duodenal ulcer is present, elective pyloroplasty and vagotomy are carried out before transplantation. Routine barium meals are performed following transplantation. Only by earlier recognition of the presence of peptic ulcer will the high morbidity rate resulting from its complications be reduced.

Collagen biosynthesis in normal and hypertrophic scars and keloid as a function of the duration of the scar

R. D. PETER CRAIG, J. DAVID SCHOFIELD AND DAVID S. JACKSON*

SUMMARY

The rates of collagen biosynthesis and the tissue concentrations of collagen in normal scar, hypertrophic scar and keloid were determined as a function of the duration of the lesions. The rate of collagen synthesis in normal scar was approximately constant between 6 months and 20 years after the initial wounding, but in both hypertrophic scar and keloid the rate was initially approximately twice that in normal scar, and 2–3 years after wounding it fell to approximately the same level as in normal scar. The tissue concentration of collagen appeared to be relatively constant in normal scar with respect to the time elapsed after wounding, but in both types of abnormal scar it was initially somewhat lower than normal scar and then rose to values higher than in normal scar after about 2–3 years. Since similar results were obtained for both types of abnormal scar in terms of the rates of collagen biosynthesis with respect to the time elapsed after wounding and also in terms of the tissue concentrations of collagen, this may indicate that the events in the pathogenesis of both abnormal scar types are similar. The results also raise the possibility that the formation of both types of abnormal scar may occur in two phases: an initial phase characterized by abnormally high rates of collagen biosynthesis, and a later phase characterized by essentially normal rates of collagen biosynthesis.

RECENT studies have indicated that the excessive accumulation of collagen seen in hypertrophic scar and keloid may, at least in part, be due to abnormally high rates of synthesis of this protein compared with normal scar (Cohen et al., 1971; Fleckman et al., 1973; Craig et al., 1975). Determination of the activity of the enzyme collagen proline hydroxylase, which catalyses the conversion of peptide-bound proline to hydroxyproline during collagen biosynthesis, and the activity of which is often regarded as an index of the rate of collagen synthesis, has shown that it is markedly elevated in both abnormal scar types, suggesting increased rates of synthesis (Cohen et al., 1971; Fleckman et al., 1973). We have measured the rate of collagen synthesis in normal and abnormal scars using the method described by Uitto (1970), in which the incorporation of radioactivity into non-diffusible peptide-bound hydroxyproline by tissue minces incubated with [^{14}C]-proline *in vitro* is determined. In agreement with the conclusions from measurement of the activity of proline hydroxylase, we observed that the rate of collagen biosynthesis, as measured by Uitto's technique, was significantly elevated in both abnormal scar types compared with that in normal scar (Craig et al., 1975), although we did not observe such dramatic increases in hydroxyproline synthesis as were observed for the increases in proline hydroxylase activity in the abnormal scar types.

In the present study we have again made use of the technique described by Uitto (1970) to determine the rates of synthesis of collagen in normal and hypertrophic scar and keloid with respect to the time elapsed after the initial wounding. We have also determined the tissue concentrations of collagen in the different scar types as a function of duration of the wound. Our results again indicate that the abnormal scars are biochemically different compared with normal scars, but the events occurring during the development of both hypertrophic scar and keloid appear to be similar and these observations may indicate that these two lesions are manifestations of the same basic defect, as discussed previously by Peacock et al. (1970).

Materials and methods

Determination of the rate of collagen biosynthesis

The rate of collagen biosynthesis in normal scar, hypertrophic scar and keloid was determined by measuring the rate of incorporation of radioactivity into non-dialysable hydroxyproline by excised tissues incubated *in vitro* with L-[^{14}C]-proline, according to the method of Uitto (1970). Hydroxyproline is found almost exclusively in collagen, constituting about 14 per cent of the dry weight of the protein, and the amounts of this imino acid are relatively constant in collagens from various tissues in humans (Eastoe, 1967; Schofield et al., 1971). The rate of hydroxyproline formation is therefore considered to be a good indication of the rate of collagen biosynthesis. Also, hydroxyproline is not directly incorporated into collagen polypeptides but rather arises through enzymic hydroxylation of certain proline residues after their incorporation into the growing polypeptide chains, and hence the radio-labelled precursor with which one incubates the tissues is proline rather than hydroxyproline.

Scar tissue was obtained during surgery and was transferred quickly to the laboratory in ice cold normal saline. Subcutaneous fat and epidermis were trimmed off and the remaining tissue was minced finely with scissors to approximately 0·5-mm diameter

pieces. Aliquots of the minced tissues (100 mg wet weight) were then incubated with L-[^{14}C]-proline for 18 hours and the radioactivity incorporated into non-diffusible peptide-bound hydroxyproline was determined as described previously (Uitto, 1970; Craig et al., 1975).

Determination of tissue concentration of collagen

The tissue concentration of collagen in the different scars was determined again by making use of the fact that hydroxyproline occurs almost exclusively in this protein. Aliquots of tissue were hydrolysed in 6 M-HCl and the hydroxyproline in the hydrolysates was determined according to the method of Stegemann and Stalder (1967).

Results

Collagen biosynthesis in normal and hypertrophic scars and keloid in relation to time elapsed after wounding

Our previous results (Craig et al., 1975) indicated that incorporation of radioactivity into hydroxyproline is linear for up to 18 hours using Uitto's (1970) technique, and that the body site from which scar tissue was taken had relatively little influence on the rate of collagen synthesis. The tissues used in the present study were from a number of different sites and an incubation time of 18 hours was used throughout.

Although we previously observed that the rate of synthesis of collagen in both abnormal scar types was significantly elevated compared with normal scar (Craig et al., 1975), no regard was taken of the effect of the duration of the lesion on the rate of synthesis in that study. The results of determination of the rates of collagen synthesis as a function of the duration of the various types of lesion are presented in *Fig.* 1. Each point represents the mean value for the amount of label incorporated into non-diffusible peptide-bound hydroxyproline by replicate 100-mg aliquots (not less than 3) of tissue minces of the same scar sample, and each sample was derived from a different patient. The values for the individual aliquots from each scar sample were always found to be within ±10 per cent, or better, of the mean value. The regression lines in *Figs.* 1*a* and 2*a* were calculated by the method of least squares.

When collagen synthesis was examined in normal scar at different times after wounding it was found that the rate of synthesis was quite constant between 6 months and 20 years (*Fig.* 1*a*). The results with hypertrophic scar and keloid, however, contrasted markedly with those obtained with normal scar. In both types of abnormal scar the rate of collagen synthesis over the first 2–3 years was approximately twice as high as in normal scar (*Fig.* 1). After 2–3 years, however, the rate of collagen synthesis in both abnormal scar types fell to approximately the same level as in normal scar, that is to approximately 50 per cent of the early values.

Tissue concentration of collagen in normal and hypertrophic scars and keloid in relation to time elapsed after wounding

A comparison of the tissue concentrations of collagen in normal and hypertrophic scars and keloid was made by determining the amount of hydroxyproline present in acid hydrolysates of the tissue samples. These results indicated that the tissue concentration of collagen in normal scars (*Fig.* 2*a*) appeared to be relatively constant with respect to the time elapsed after wounding (approximately 1·5 mg hydroxyproline/100 mg wet tissue). In hypertrophic scar and keloid, however, the initial values were approximately 1·1 and 0·8 mg respectively, but they increased such that at 4 years after wounding the values for hypertrophic scar and keloid were approximately 2·3 and 2·7 mg respectively (*Fig.* 2*b*, *c*). Hence, both the rate of collagen synthesis and the tissue concentration of collagen were observed to vary considerably with respect to time elapsed after wounding in the abnormal scars, whereas in normal scar these parameters appeared to be relatively constant. Furthermore, the fall in the rate of synthesis in both hypertrophic scar and keloid from approximately the same high value to about the same approximately normal value, and the increase in the collagen content of the abnormal scars from approximately normal values to values significantly higher than normal, both occurred at about the same time, that is about 2–3 years after the initial wounding.

Discussion

Determination of the rates of collagen biosynthesis in normal scar, hypertrophic scar and keloid, either by measurement of the activity of the enzyme collagen proline hydroxylase (Cohen et al., 1971; Fleckman et al., 1973) or by measurement of the incorporation of radioactivity into hydroxyproline (Craig et al., 1975), have suggested that abnormally high rates of biosynthesis of collagen may be a contributory factor leading to the formation of the abnormal scars. Enzyme activity was approximately fourteen times higher in keloid, and was approximately four times higher in hypertrophic scar, when compared with normal scar (Cohen et al., 1971). Although we also observed an increased rate of collagen synthesis in the abnormal scars, as determined by measurement of the incorporation of radioactivity into hydroxyproline upon incubation of tissues with [^{14}C]-proline *in vitro*, the increases were somewhat less than twofold in both abnormal scar types compared with normal scar (Craig et al., 1975). However, these studies were undertaken without regard to the duration of the lesion.

In the present study the rate of collagen synthesis was examined with respect to the time elapsed after wounding (*Fig.* 1). Normal scar synthesized collagen at a relatively constant rate (*Fig.* 1*a*), but in both hypertrophic scar and keloid the rate of collagen synthesis during the first 2–3 years after wounding was approximately twice as high as in normal scar and subsequently fell to the level found in normal scar (*Fig.* 1*b*, *c*).

The tissue concentration of collagen in normal scar was relatively constant with respect to the time elapsed after wounding, whereas in both abnormal types of scar there appeared to be a continuous increase up to at least 4 years (*Fig.* 2). Such changes in the collagen content of keloid were not observed in a previous study (Harris and Sjoerdsma, 1966). However, the minimum period which elapsed between wounding and examination of the tissue was 2 years in that study, and it is possible that such changes that might occur had already done so in the 2 individuals examined at that time. It has been assumed in the present work and in that of Harris and Sjoerdsma (1966) that the hydroxyproline content of the collagen in each type of scar is the same. This seems to be a reasonable assumption in view of the constancy of the hydroxyproline contents of collagens from a wide variety of human tissues such as skin, tendon and bone (Eastoe, 1967; Schofield et al., 1971).

Peacock et al. (1970) have made the point that hypertrophic scar and keloid formation may be manifestations of the same basic defect, and it is interesting in this respect that in both abnormal scar types the pattern of the changes observed both in the rates of synthesis and in the tissue concentrations of collagen are very similar (*Figs.* 1, 2). These observations may indicate that the events leading to the pathogenesis of hypertrophic scars and keloids are essentially similar.

In normal scar it is apparent that the rates of synthesis and degradation of collagen are in equilibrium since there is no excessive accumulation of collagen in either case. Initially the rate of collagen synthesis in hypertrophic scar and keloid is twice as high as in normal scar (*Fig.* 1), but 2 or 3 years later falls to the same level as in normal scar. Despite this fall in rate of collagen synthesis there is a continued excessive deposition of collagen, which suggests that there is also deficiency in the mechanism of collagen degradation in the two abnormal tissues. Examination of the collagenase produced by explants of hypertrophic scar, keloid and normal skin (Milsom and Craig, 1973) revealed no significant differences either in the amount of the enzyme produced or in the nature of the enzyme compared with normal skin, although a comparison between the two abnormal scar types and normal scar was not made in that study. It is, however, possible, as suggested by Milsom and Craig (1973), that activation of procollagenase, the inactive zymogen of collagenase, is suppressed in the abnormal scars *in vivo*. This could occur either through the presence of a suppressor of the enzyme(s) which activate procollagenase or through the presence of a defective activator enzyme, and a recent report (Harper and Gross, 1974) has indicated that the activity of an activator of procollagenase is indeed low in keloid and hypertrophic scar. It would appear, therefore, that the degradation of collagen, as well as its biosynthesis, is defective in keloid and hypertrophic scar.

These observations raise the possibility that there may be two phases in the production of hypertrophic scar and keloid, the first being characterized by abnormally high rates of collagen synthesis and possibly abnormal degradation of collagen, and the second being characterized by essentially normal rates of collagen synthesis and presumably decreased degradation.

A technique for re-exploration of the saphenofemoral junction for recurrent varicose veins

ARTHUR K. C. LI*

SUMMARY

A safe and simple method is described for re-exploration of the saphenofemoral junction in patients with recurrent varicose veins following incomplete 'Trendelenburg operation'.

A MAJOR cause for recurrent varicose veins is inadequate groin dissection, with failure to ligate flush with the saphenofemoral junction (Hæger, 1967; Nabatoff, 1969; Lofgren and Lofgren, 1971). Re-exploration of this region is often beset with difficulties from previous scar tissue encasing the delicate dilated varices (Stein, 1967). A simple and expeditious method is described here which will overcome these dangers. This approach is familiar to vascular surgeons who use it in the exposure of the vessels at the groin for vein graft bypass operations.

Technique

The common femoral artery is first palpated and defined at the groin. The previous incision, if already correctly placed, may be used but it must be extended laterally over the femoral pulse (*Fig.* 1). The dissection begins at the lateral end of the incision, which is deepened through the fascia to expose the femoral artery within the femoral sheath. By incising the femoral sheath over the artery longitudinally for approximately 5 cm and then taking the dissection medially, the femoral vein can be readily displayed both above and below the saphenofemoral junction (*Fig.* 2). Since the previous operation will not have properly exposed the saphenofemoral junction and the femoral vein, the present plane of dissection will be deep to the scar tissue and therefore little difficulty is encountered.

Once the femoral vein and saphenofemoral junction have thus been exposed and the saphenous stump has been gently dissected from the surrounding tissues using a curved artery forceps such as a Fraser, an aneurysm needle with a silk ligature can be passed safely around the saphenofemoral junction, after which flush ligation with the femoral vein can be carried out (*Fig.* 3). The stump can be similarly ligated and the junction divided, thereby achieving control of the main source of retrograde incompetence.

The remaining dilated varices in the scar can be dealt with in two ways. A 'running stitch' through the scar tissue can be used to obliterate these plexuses of veins, or alternatively the scar tissue interlaced with the varices can be divided along the line of the previous incision between haemostatic clamps (*Fig.* 4). As the femoral vein is now well exposed, it is simple to check that no aberrant superficial veins join it distal to the saphenofemoral junction, and the deep external pudendal vein can be ligated.

Discussion

The majority of difficulties encountered in re-exploration of the saphenofemoral junction occur in patients in whom the previous incision had been correctly placed (Pratt, 1971) and attempts made to ligate the tributaries. It has been suggested that a higher incision should be made just below the inguinal ligament so that further dissection would be through normal tissue (Luke, 1954; Dodd and Cockett, 1956).

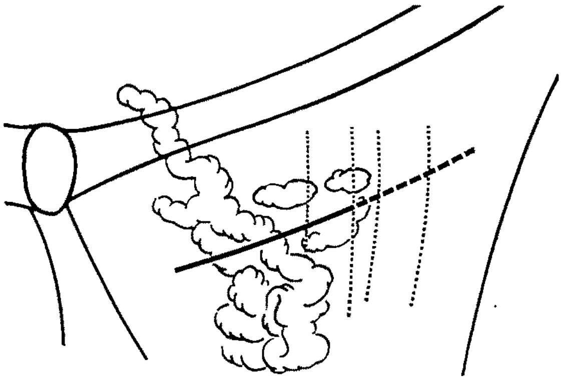

Fig. 1. The incision placed over the femoral pulse.

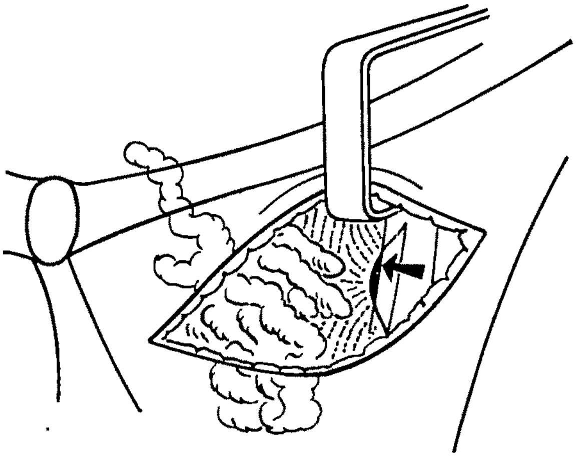

Fig. 2. Longitudinal exposure of the femoral artery in the femoral sheath.

Present address: Academic Department of Surgery, Royal Free Hospital, London.

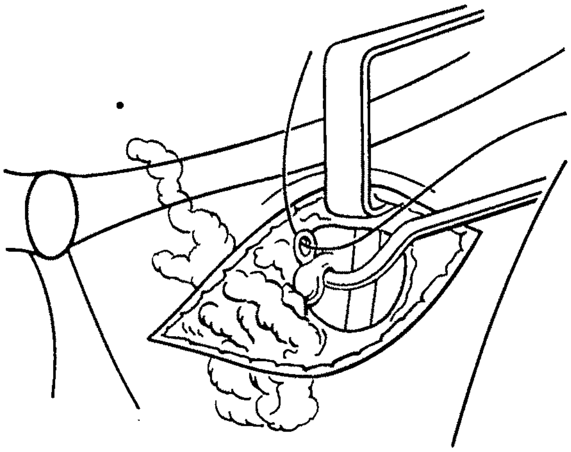

Fig. 3. Exposure of the saphenofemoral junction and flush ligation with the femoral vein.

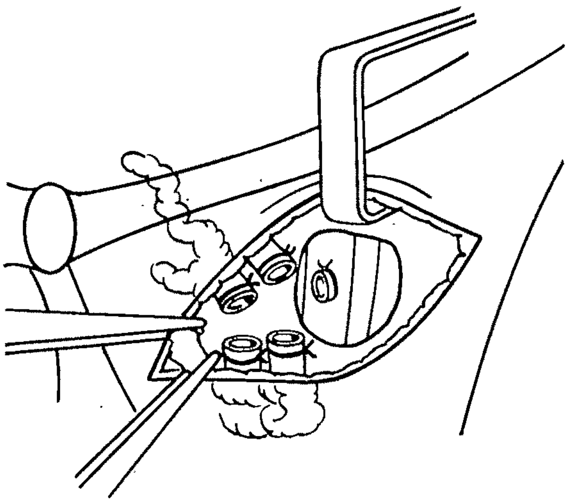

Fig. 4. Ligation of the tributaries.

However, when the previous incision is already high it may afford little room to manœuvre.

Emphasis has also been placed on seeking the femoral vein either from above the saphenofemoral junction (Dodd and Cockett, 1956) or from its medial aspect (Halliday, 1970). In the midst of scarred and adherent tissue it is far safer to dissect on to a pulsating artery than a compressible vein with all its ramifications of tributaries. Furthermore, early exposure of the femoral artery allows prompt control of the superficial external pudendal artery if necessary.

With previous techniques of re-exploration, troublesome bleeding may occur from the posterior aspect of an in-bulging varix situated further distal to the saphenofemoral junction. By the method suggested, early control of the femoral vein above and below that junction is obtained should it be necessary, and thus the haemorrhage can be contained.

In conclusion, the advantages of the technique described are threefold. First, there is a single incision instead of two. This is important as there is often an element of cosmetic complaint in patients with varicose veins. Secondly, the initial exposure is that of an artery which makes the operation simpler and safer and more expeditious than the hazardous exposure of a compressible vein in a small field. Lastly, the dissection is through normal tissue, thus avoiding the cicatrix with its enmeshed varices, and allows early control of the femoral vein above and below the saphenofemoral junction should it be necessary. This method of dealing with groin recurrences has been performed on more than 30 patients at St Mary's Hospital, London, and the results have been entirely safe and satisfactory.

Parathyroid identification by methylene blue infusion

DONALD L. GORDON, MOHAN C. AIRAN, WILLIAM THOMAS
AND LEON H. SEIDMAN*

SUMMARY

The intravenous infusion of methylene blue was investigated as a procedure that would identify parathyroid glands during operation in 17 patients with primary hyperparathyroidism. The dye was found to stain all adenomas, most hyperplastic glands and occasionally normal parathyroid glands. In addition, the frequency of glandular staining was directly related to the size of the gland, although size and histology may have been independent variables. Methylene blue infusion is a safe effective method of localizing abnormal parathyroid glands.

PARATHYROID gland localization is a perplexing problem to many surgeons. A meticulous exploration of the neck must be performed in primary hyperparathyroidism with every effort made to identify, by inspection and histological confirmation, all parathyroid tissue (Black and Haff, 1970). Detection is particularly difficult because of the small size of these glands, which are normally less than 7 mm in greatest diameter (Castleman, 1952). Atypical sites and variable numbers of parathyroid glands compound the surgeon's problem.

Clinical interest was attracted by the report of Klopper and Moe (1966) that intravenous infusion of toluidine blue distinctly stained the normal parathyroid glands of dogs. This was confirmed by Hurvitz et al. (1967), and the technique was successfully extended to humans in a subsequent report (Hurvitz et al., 1968). However, arrhythmias and cardiac arrest attributable to the dye eventually resulted in a decrease in its use (Pridgin et al., 1969; Yeager and Krementz, 1969; Singleton and Allums, 1970). An alternative was reported by Dudley (1971), who described parathyroid staining without complications in 17 patients after methylene blue infusion.

Methylene blue was infused by us in patients operated upon for primary hyperparathyroidism in an attempt to correlate the ability of the parathyroid gland to stain blue with its size and histology.

Patients and methods

Methylene blue was infused during neck exploration in 17 consecutive patients with primary hyperparathyroidism. Patients who had had previous operations on the neck were excluded from the study. A dose of 5 mg/kg body weight (230–500 mg) of a 1 per cent solution of methylene blue was prepared on the morning of operation in 500 ml of 0·9-N saline. The infusion, which lasted 45–60 minutes (average 50 minutes), was timed to end 15 minutes before completion of the dissection to the plane of the pretracheal fascia.

Each parathyroid gland was measured *in situ* after complete dissection but before biopsy. Note was made of the colour of the gland. When it was uncertain that a trace of dye was actually present it was considered to be absent. An attempt was made to biopsy all parathyroid glands. Most patients had all or parts equivalent to 3 parathyroid glands removed for therapy of primary hyperparathyroidism. Any extraparathyroid tissue that stained blue for longer than 45 minutes after the end of the infusion was biopsied.

Blood pressure, pulse, respiratory rate and ECG were monitored before, during and after the operation. Serum calcium levels were measured before operation and usually at daily intervals afterwards to assess the completeness of the operation.

Results

Primary hyperparathyroidism was confirmed in all the patients by tissue diagnosis and relief of hypercalcaemia within 48 hours of parathyroidectomy (Gordon et al., 1972). The final pathological diagnosis was a single parathyroid adenoma and hyperplasia in 11 patients, multiple parathyroid adenomas and hyperplasia in 2 patients, single adenoma in 1 patient and diffuse hyperplasia in 3 patients.

Sixty parathyroid glands were identified histologically while 3 additional glands were isolated but not biopsied. The staining affinity for the dye was directly related to the size of the parathyroid gland (*Table I*). Forty of the 46 (87 per cent) enlarged parathyroid glands were significantly discoloured by the dye, while only 3 of 12 (25 per cent) normal sized glands were stained. When this characteristic was correlated with the histological diagnosis, disregarding size, 16 out of 16 (100 per cent) adenomas stained, 23 out of 27 (85 per cent) hyperplastic glands stained and only 4 out of 15 (27 per cent) histologically normal glands stained blue (*Table II*). Parathyroid adenomas and enlarged hyperplastic parathyroid glands readily concentrated the dye, usually developing a dark blue colour. A less consistent colour of either a lighter blue or a violet tinge was noted in hyperplastic glands of normal size, enlarged glands that were histologically normal and glands whose size and histology were both normal. In 1 patient with an adenoma, 2 additional hyperplastic parathyroid glands were biopsied, but the staining characteristics were not noted in the record; therefore they could not be

included in the tabulations. Three additional normal sized, unstained parathyroid glands were noted but not biopsied. For this study these glands were not counted as parathyroids and are considered not to have been located. Assuming an average of 4 parathyroid glands per patient, 60 out of 68 (88 per cent) of the glands were proved by biopsy to be present. Ten parathyroid glands were not included in the tabulations due to lack of biopsy confirmation or documentation of staining characteristics or their not being found. This represented the experience in only 4 patients; the other 13 patients had all 4 glands located, the staining characteristics had been noted and they were biopsied.

There were 9 instances of non-parathyroid tissue staining blue for prolonged periods. These included two lymph nodes, the nodularity and/or cyst formation in 6 colloid goitres and the whole thyroid gland in 1 case of lymphocytic thyroiditis. No complications were noted during or following the operation that could be attributed to methylene blue.

Discussion

The diagnosis of primary hyperparathyroidism has continued to be made in most cases on the basis of persistent hypercalcaemia after exclusion of all other causes of this abnormality. However, a change in the surgical approach has gradually occurred. This evolved as a result of observations upon patients with persistent hypercalcaemia following removal of what was thought to be a solitary parathyroid adenoma. At re-exploration considerable variability in the size of the histologically abnormal glands was noted. In addition, as multiple glands were biopsied more routinely during the initial operation, a changing incidence of parathyroid hyperplasia with or without adenoma was diagnosed more frequently (Reinhoff et al., 1968; Straus and Paloyan, 1969; Egdahl, 1970; Haff et al., 1970). This had made it more imperative for accurate parathyroid localization techniques to be developed.

Preoperative localization of abnormal parathyroid glands has been reported using selenomethionine-75 scanning (DiGiulio and Morales, 1969), arteriography (Doppman et al., 1969) and venography with parathormone sampling of the venous effluent (Aurbach et al., 1973). Of these procedures, only angiography followed by selective venous parathormone sampling is able to distinguish between adenoma and hyperplasia. Yet even these procedures do not allow precise localization of adenomas (Aurbach et al., 1973; Shimkin and Powell, 1973). The ideal method should result in visualization of all the parathyroid glands, or at the very least all the abnormal glands. It should be both safe and readily available for use at large centres as well as smaller institutions. Intravenous infusion of methylene blue meets these criteria.

Parathyroid staining by methylene blue occurred in 42 out of 58 (76 per cent) histologically proved, parathyroid glands. This probably represents a modest overestimate of the gross staining capabilities of the dye. Three of the remaining glands were found unstained but not histologically confirmed as parathyroid tissue, while 5 other glands were not located. In view of the fall of serum calcium to normal levels in these patients, the glands that were not found at operation were presumably either normal or atrophic histologically, or were not present. This assumption is supported by our data, which show that the staining property of the parathyroid gland is directly related to its size and that the histologically adenomatous or hyperplastic gland stains more readily than the normal gland. This could be due to increased avidity of metabolically hyperactive, parathyroid cells for the dye. Conversely, glandular staining may simply be a function of increased cellular concentration in adenomatous or hyperplastic glands that lack the fat content of normal or atrophic glands. However, the glandular size and histology may vary independently in relation to tissue staining. Dudley (1971) noted intense staining of parathyroid adenomas, while normal glands were a dusky slate blue. While we can confirm these observations, we chose to classify as unstained any parathyroid glands in which a definite colour change was not obvious. We considered that such minimal staining of glands was not adequate for localization at operation.

Thiazide dyes (methylene blue, toluidine blue, thionine, Azur A) are taken up preferentially in certain tissues of the body (Dudley, 1971; Normann and Normann, 1972). The tissue distribution of toluidine blue has been studied most extensively. This dye localizes in parathyroid, heart, pancreas and thyroid tissue, although there appear to be differences between species (DiGiulio and Morales, 1969; Archer et al., 1972). Differing rates of tissue clearance are a useful characteristic of the dye (DiGuilio and Morales, 1969; Mortenson and McRae, 1970; Archer et al., 1972). This permits prolonged searching for stained parathyroid glands, while the colour of the thyroid has already returned to normal (Hurvitz et al., 1968; (Tardy and Tenta, 1971). However, premature infusion of toluidine blue may result in loss of parathyroid staining by the time the preliminary dissection of the neck is completed. Indeed, in an unpublished study we have found that 45–60-minute infusions of toluidine blue, terminated 15 minutes before parathyroid visualization, resulted in more frequent parathyroid staining than similar dye infusions concluded 2–4 hours prior to visualization. We used this experience when methylene was substituted for toluidine blue, because of the reported cardiotoxicity of the latter dye (Pridgin et al., 1969; Yeager and Krementz, 1969; Singleton and Allums, 1970). Methylene blue was found to be approximately equally effective in parathyroid localization during operation for primary hyperparathyroidism. Other similarities of these dyes are characteristically transient staining of muscle and thyroid tissue, as well as their ability to stain pancreatic tissue. Indeed, methylene blue has been reported to stain deeply a tumour of the pancreas secreting an insulin-like substance (Gordon et al., 1974).

Methylene blue infusion decreased the time needed for identification of the parathyroid glands. Staining of non-parathyroid tissue was limited to lymph nodes showing reactive hyperplasia and to abnormal thyroid tissue. This presented no problem, merely resulting in an occasional additional biopsy taken for frozen section. No complications attributable to methylene blue infusion were experienced. Therefore, we conclude that methylene blue administered by intravenous infusion is a safe effective method of localizing abnormal parathyroid tissue although it may occasionally also stain normal or atrophic glands significantly.

Selective surgery for abdominal stab wounds

A. THAVENDRAN, A. VIJAYARAGAVAN AND RUDRA RASARETNAM*

SUMMARY

The value of selective surgery for abdominal stab wounds was assessed in a prospective study of 226 patients admitted over an 18-month period. Two died soon after admission and before operation, the indications for which were signs of peritoneal irritation or haemorrhage, evisceration of bowel and omental protrusion. Of the 226 patients, 113 were selected for immediate surgery, which was carried out within 3 hours of admission. There were 12 deaths (10·6 per cent). Of the 111 patients initially selected for observation, 47 (42·3 per cent) underwent delayed operation with 4 deaths (8·5 per cent), but in only 1 (2·1 per cent) of these patients could the delay have influenced the adverse result. There were no deaths in the 64 patients treated conservatively. The overall mortality rate for patients who were initially selected for observation was 3·9 per cent.

One hundred and fifty patients underwent laparotomy, positive findings justifying operation being present in 134 (89 per cent). Six patients required thoracotomy for concomitant thoracic injuries, including 2 patients who required cardiorraphy. Four other patients required combined thoracic and abdominal exploration. The selection of patients for either conservative or operative management was based entirely on clinical criteria; abdominal X-rays were not helpful in the early diagnosis of visceral lesions. The indications for operation were evident within 12 hours of admission in 156 of the 160 patients who were treated surgically.

A substantial reduction in the incidence of 'negative laparotomy' can be made by this process of selection, and without an associated increase in the morbidity and mortality rates.

UNTIL recently laparotomy has been advocated for all stab wounds of the abdomen where peritoneal penetration is present, or suspected of being present, for fear that without exploration, visceral injury requiring repair might be overlooked. In view of the large number of negative explorations that were carried out, Shafton (1960) advocated a policy of selective conservative management, a view that has slowly gained acceptance in some centres, since with careful clinical evaluation many unnecessary operations are avoided and without an associated increase in the morbidity and mortality rates (Rothschild and Treiman, 1966; Ryzoff et al., 1966; Friedman, 1968; Richter and Zaki, 1970). Controversy, however, still exists, with many surgeons favouring routine laparotomy in all abdominal stab wounds in view of the difficulties of early diagnosis of visceral lesions (Goldman et al., 1962; Maynard and Oropeza, 1968).

This paper is based on a prospective study of patients admitted to the Accident Service of Colombo General Hospital during the 18-month period commencing in May 1972. A policy of selective surgery for abdominal stab wounds was practised, the criteria for which are described below.

Patients and methods

Two hundred and twenty-six consecutive patients with abdominal stab wounds were admitted during the period of the trial; 72 also had thoracic injuries. There were 213 men and 13 women, with ages ranging from 9 to 73 years, the maximum incidence being in the third and fourth decades. Multiple stab wounds were not unusual and were associated with a rising mortality rate, particularly when distributed over the whole of the trunk. In the critically ill patient with multiple stab wounds who required immediate exploration to arrest haemorrhage there was a danger that a second significant wound might be overlooked, as happened in 1 patient who underwent immediate cardiorraphy for cardiac arrest due to tamponade, only to succumb 3 hours later from an unrecognized injury to the right kidney.

In abdominal injuries no one sign could be said to be diagnostic, with the possible exception of hypotension, in the early phase after injury, but a reasonable assessment could be made on the whole clinical picture. Abdominal guarding was frequently present, particularly around the external wound, but in the absence of visceral injury it tended to be localized and to regress with time. Rigidity and abdominal distension were usually late in onset and indicated peritonitis. Bowel sounds were almost invariably present soon after injury even in the presence of visceral perforation. On the other hand, they were absent in only 11 patients, 10 of whom had visceral injuries, while the eleventh was transferred to this hospital 51 hours after being stabbed, and had ileus due to a retroperitoneal haematoma. Stab wounds of the lower chest, particularly on the left, were often associated with upper abdominal tenderness and guarding, and were the most difficult diagnostic problems. Taking into account the interval since injury, repeated clinical examination, preferably by the same individual, was the best aid for accurate diagnosis. Abdominal X-rays were useless, as in no case with positive radiological features was the diagnosis or the necessity for exploration not already obvious on clinical grounds.

The indications for laparotomy were signs of peritoneal irritation or haemorrhage, a systolic blood pressure of 80 mm Hg or less and evisceration of

bowel and omental protrusion. There was some doubt early in the trial as to whether omental protrusion alone should be a definite indication for laparotomy, but analysis of the results shows that these patients have the same incidence of visceral injury as the rest of the patients who underwent laparotomy (*Table I*). The presence of any of these criteria was an indication for immediate exploration, the remainder being kept under observation for the possible later development of such criteria.

Resuscitation was carried out in all patients before operation, with the exception that when significant haemorrhage was suspected, exploration and resuscitation were carried out simultaneously. A systolic blood pressure of 80 mm Hg or less in patients with abdominal trauma who were seen within an hour of injury was considered indicative of a vascular lesion, requiring immediate exploration.

Seventy-two patients had thoraco-abdominal injuries, 37 having separate external wounds in the chest and abdomen, the remaining 35 having diaphragmatic penetration, but only one of the latter presented with a hernia. All but one of the patients with diaphragmatic penetration had external chest wounds, and although this occurred more frequently with lower thoracic stab wounds, it was also present in 8 patients with wounds in the upper thorax.

Results

Two patients admitted in a critical state died before operation; one was admitted with absent vital signs due to perforating injuries of the heart, diaphragm, liver, stomach and pancreas, and the other patient was in severe shock due to an aortic injury.

One hundred and sixty of the 226 patients underwent surgery: 150 laparotomies, 6 thoracotomies and 4 thoracolaparotomies (*Table II*). Laparotomy was associated with a 7·3 per cent mortality rate, while combined thoracic and abdominal exploration carried a prohibitive mortality of 75 per cent. One hundred and thirteen of the patients had criteria justifying immediate exploration which was carried out within 3 hours of admission. There were 12 deaths in this group, a mortality of 10·5 per cent, but this figure also includes the patients who required thoracotomy. The remaining 111 patients were initially selected for conservative treatment, but 47 of them subsequently required abdominal exploration, which was carried out between 3 and 22 hours after admission (*Table III*). There were 4 deaths in the patients who underwent delayed operation (8·5 per cent), the operations in these 4 being carried out between 6 and 10 hours after admission. These patients form the crucial group in the evaluation of selective surgery for abdominal stab wounds. In only one of them could the delay have affected the result—a patient with a stab wound in the third right intercostal space in the axillary line who had no evidence of an abdominal lesion at admission but 7 hours later required exploration for a penetrating liver injury. When the clot overlying the hepatic wound was dislodged brisk haemorrhage recommenced and was controlled by suture. He died 3 days later because of lack of blood for transfusion, and the result may well have been different had it been available. The delay of up to 10 hours before surgery had no bearing on the other 3 deaths. One patient with multiple stab wounds was transferred to this hospital 51 hours after being attacked; he presented with abdominal distension, ileus and incipient uraemia due to a retroperitoneal haematoma, and he had a cardiac arrest on the operating table. Another patient died 14 days postoperatively of septicaemia due to infection in a retroperitoneal haematoma. The final patient, who had a lower thoracic stab wound, was found at laparotomy to have an anterior gastric wound which had not penetrated the lesser sac. He bled to death from an unrecognized mucosal tear on the posterior gastric wall and must be considered a technical error.

Table I. SIGNIFICANCE OF EVISCERATION OF BOWEL AND OMENTAL PROTRUSION

	Omental protrusion	Evisceration of bowel
No. of patients	48	10
No. died	1	0
Operation	47	10
Operative deaths	0	0
Negative laparotomy	5	2

Table II: MANAGEMENT

	All abdominal injuries			Thoraco-abdominal injuries		
	No.	Died	%	No.	Died	%
Total	226	18	7·9	72	10	13·8
No operation	66	2	3·0	17	2	11·7
Laparotomy	150	11	7·3	45	3	6·6
Thoracotomy	6	2	33·3	6	2	33·3
Thoracolaparotomy	4	3	75·0	4	3	75·0
Negative laparotomy	16	0	—	4	0	—

The figures for thoraco-abdominal injuries are also included in those for all abdominal stab injuries.

Table III: MORTALITY IN RELATION TO THE TIME INTERVALS BETWEEN INJURY AND ADMISSION AND OPERATION

	Injury to admission		Admission to operation		
Time	No.	Died	No.	Died	Negative laparotomy
0–30 min	65	6	7	4	1
31–60 min	49	3	26	4	2
1 h 1 min–3 h	43	1	80	4	6
3 h 1 min–6 h	46	5	29	0	4
6 h 1 min–12 h	15	1	14	4	2
12 h 1 min–36 h	2	0	4	0	1
Over 36 h	2	1	0	0	0
Not known	4	1	0	0	0

Negative laparotomy

A retrospective analysis was made of all the patients undergoing exploration in an effort to determine whether operation had been necessary. Laparotomy was classed as necessary if a visceral lesion requiring repair was present, if haemostasis had to be effected or if the peritoneal cavity contained more than 250 ml of blood irrespective of whether the source of bleeding was identified or even if active bleeding had ceased. An operation was considered to be a 'negative laparotomy' when no visceral lesion required repair, as in superficial liver injuries that had ceased bleeding, or if the peritoneal cavity contained less than 250 ml of blood without evidence of continuing haemorrhage. Peritoneal penetration alone was considered to be a negative laparotomy, as was a retroperitoneal haematoma not requiring haemostasis. Sixteen of the 150 laparotomies (10·6 per cent) were judged by these criteria to be negative, and it is interesting that they were evenly spaced out throughout the whole 22-hour period after admission during which the operations were performed (*Table III*).

Length of hospital stay

The average duration of hospital stay for patients treated conservatively and by operation was 5 and 12 days respectively. The morbidity in the conservative group was negligible.

Discussion

Mandatory laparotomy has been accepted practice for penetrating abdominal wounds for many years. In a retrospective analysis Shafton (1960) found that in the absence of definite clinical criteria there was a high incidence of negative explorations in abdominal stab wounds. The policy of selective surgery can be justified only if there is no mortality and reduced morbidity in patients treated conservatively, and also that any delay in operation inherent in this policy of 'wait and see' does not adversely affect the result. Subsequent reports have confirmed that these objectives may be achieved by careful clinical evaluation (Ryzoff et al., 1966; Cameron, 1970; Richter and Zaki, 1970). In the present series of 226 patients clinical evidence to warrant surgery was present at the time of admission in 113 (50 per cent), and in 43 of the 47 patients who underwent delayed surgery it was present before 12 hours had elapsed. In only 4 patients were the signs so inconclusive that operation had to be delayed up to 22 hours. Delay could be incriminated in the result in only 1 case who might have recovered if blood had been available at some time during the 3-day postoperative period. Sixty-four patients (28·2 per cent) were treated conservatively without any fatality and with reduced morbidity and period of hospital stay.

The selection of patients for either conservative or operative treatment is the most difficult aspect of management. Goldman et al. (1962) and Maynard and Oropeza (1968), who advocated mandatory laparotomy, found that 57 and 42 patients in their respective series who had negative physical signs had visceral injuries at operation, and consequently doubted the value of clinical assessment. The injection of radio-opaque solutions into the wound (Smithwick et al., 1968; Haddad et al., 1970) and exploration of the wound under local or general anaesthesia (Goldman et al., 1962; Roberts and Lavelle, 1966; Roy, 1974) have been used in an effort to delineate peritoneal penetration, and thereby reduce the incidence of negative laparotomy, but there is no convincing evidence that it will make a substantial reduction as the more important reasons for operation are not assessed. Negative laparotomy is inevitable in penetrating abdominal trauma, even with selective surgery, but its incidence can be reduced with such evaluation. Attempts to reach statistical perfection must be forsaken, and a negative exploration rate of 10 per cent seems reasonable. The argument against mandatory laparotomy would be less impressive were it not for the complications associated with it. Emergency surgery in an unprepared patient carries a slight morbidity and mortality, and a rate as high as 6·3 per cent for the latter has been reported (Maynard and Oropeza, 1968).

Acknowledgements

We have pleasure in thanking the resident surgeons of the Accident Service, Colombo General Hospital, for allowing us to include patients treated by them; Mr Y. R. Karunaratne for help with the analysis of data; and Miss Nafeeza Mousajee and Miss B. Ranatunga for secretarial help.

This work was partly supported by a grant from the National Science Council of Sri Lanka.

Reviews and notices of books

Handbook of Obstetrics and Gynaecology

Ralph C. Benson, Portland, Oregon. Fifth edition. 178 × 105 mm. Pp. 770+ix. Illustrated. 1974. Los Altos, California: Lange Medical Publications. $8.

This is a well-produced, convenient, pocket-sized book with clear print and numerous illustrations which covers the whole field of obstetrics and gynaecology in just under 800 pages. It provides a great deal of information about many topics in a rather superficial fashion yet gives no references to the literature or suggestions for further reading.

As the Preface points out, it is meant to supplement rather than substitute for more complete textbooks on the subject, but at the same time it is not written as a critical digest. Almost everything gets a mention, but sometimes little more than that. Methods of diagnosis or treatment are sometimes listed rather uncritically so that although an uninformed reader might know what was available he would not know what was appropriate.

Perhaps these comments are hypercritical, for the book certainly provides much information about obstetrics and gynaecology and does refer to many recent advances. Some parts are particularly good, including chapters on the emotional aspects of pregnancy and psychosomatic problems in gynaecology. The concise and up-to-date section on contraception is also first rate. However, nowadays, when obstetricians try to avoid performing difficult vaginal delivery, it is surprising that the sections on the management of abnormal labour should pay so much attention to describing many different types of obstetric forceps, as well as various obstetric manipulations now rarely used. The author's statement that classic Caesarean section will often be performed for placenta praevia or in obstetric emergencies such as abruptio placentae or prolapsed cord is at variance with the views of most obstetricians in this country, as would be his recommendation that routine appendicectomy should be performed at Caesarean section.

Some of the gynaecological approaches recommended in the book also appear to differ from current British practice. For example, in the investigation of the patency and function of the Fallopian tubes in infertile women, pride of place is given to insufflation, while hysterosalpingography is only mentioned very briefly, and laparoscopy not at all in this section.

The value of this book is that it allows the reader to skim through a wide-ranging but superficial account of obstetrics and gynaecology in a relatively short time. Practising physicians might benefit from considering the approaches mentioned in it, but medical students in this country could find it difficult to absorb and not always in line with their clinical teaching.

A. C. TURNBULL

Fibre-optic Endoscopy

P. R. Salmon, Bristol. 215 × 155 mm. Pp. 237+xiii. Illustrated. 1974. Tunbridge Wells: Pitman Medical. £4·50.

This is an essential manual for all those starting out in endoscopy and of great practical help to those already established in the practice. It will be invaluable not only to clinicians but also to nurses and ancillary staff. Radiologists and pathologists will find it of interest as well. It is full of all the useful advice so often missing from books of this kind. Dr Salmon deals with all the important details in the setting up of an organization of an endoscopy service, and the care and maintenance of the expensive equipment. He also deals effectively with handling of tissues obtained during endoscopy, and there are helpful chapters on photography and the role of radiology in fibre-optic endoscopy. This is an excellent book that can be thoroughly recommended.

IAN MCCOLL

1974 Year Book of Surgery

Edited Seymour I. Schwartz, Rochester, et al. 235 × 155 mm. Pp. 525, with 172 illustrations. 1974. London: Lloyd-Luke. £9·60.

For those not familiar with the format of this series, this book is a potpourri of several hundred well-written abstracts of selected original papers of surgical interest. Each abstract is accompanied by a short avuncular comment on the merit and significance of the work. There is also a 20-page 'annual overview' which summarizes very briefly the developments thought to be most important by the six American professors of surgery who form the editorial team.

The amount of work needed to complete this volume must have been enormous. Was it worth it? Since much of the whole spectrum of surgery is covered, no single subject can be dealt with in sufficient depth to be of interest to the specialist in that subject. However, the book will be useful to the man who is keen to keep abreast of subjects other than his own or who wants to fill in those embarrassing gaps in knowledge which we all suffer when we miss an important article in one of the common journals which everyone else seems to have read.

One or two criticisms have to be made. First, there are some surprising omissions, e.g. the virtual absence of reports on gastric cancer. Next, it appears that only the English literature was considered and it is difficult to believe that no surgical advances were described in other languages. Finally, the title of the book is a trifle misleading since the literature up to February 1974 only is reviewed. Nevertheless, it provides a relatively painless way of keeping up-to-date. Prospective purchasers should note that subjects such as urology, neurosurgery and orthopaedics are dealt with in other 'Year Books'.

ALAN G. COX

The Faber Medical Dictionary

Edited Sir Cecil Wakeley, now revised by J. G. Bate, London. Second edition. 245 × 190 mm. Pp. 483. 1975. London: Faber and Faber. £6·95.

English being the accepted international language of science and medicine, a reliable and up-to-date reference work will always be needed by authors, secretaries and editors to maintain accuracy in what they write. Most of the existing medical dictionaries are American. This means that the special needs of British users are sometimes incompletely met. The new Faber now comes to their aid with a good clear explanation of nearly all essentials, especially the more recent arrivals in the medical vocabulary, such as antilymphocytic globulin, FDP's, Kveim's test, lincomycin and technetium. For those of more classical inclinations, there is the extensive etymological material that clearly explains for the interest and instruction of the red brick medical reader also the derivation of that large and still growing majority of medical terms for which the Greeks and Romans left us a concise and descriptive word basis. There is still much historical material, some of which borders on the archaic and even the mythological. Burn's blindness from sexual overactivity and Richardson's sign of persisting life in a supposed corpse both may have a kind of whimsical usefulness. Hairy tongue we mostly remember but never see, yet hairy-celled leukaemia has not been included. Chemoreceptor tissue is ably defined, but not chemodectoma. Perhaps it belongs in the fossa cároticum, mentioned in Malgaigne, but not located. Even with faults like these, which may worry overseas readers more than us at home, it is a fine effort, well produced, full of interest for browsing in, as well as for pouncing on when we need. It is good value at the price.

H. H. G. EASTCOTT

Reviews and notices of books

Surgical Forum—The Liver

Edited Rodney Smith, London. 215 × 135 mm. Pp. 163+x. 1975. London: The Butterworth Group. £2·80.

THIS volume brings together an international group of surgeons with an interest in different aspects of hepatic surgery. The book aims to capture the atmosphere of a surgical forum and each author presents a chapter after which the others are asked to comment.

In general the Editor, Sir Rodney Smith, has succeeded in his aim in that the book allows the reader a review of the approach of experts to the four subjects covered, namely cirrhosis of the liver and acute hepatic failure, liver transplantation, hepatic trauma and tumours of the liver. The book should be of value not only to the general surgeon but to specialists with an interest in liver surgery.

The chapter by Alexander Walt on hepatic trauma reflects the immense experience of the Detroit group and gives a balanced view of the subject. Professor Walt makes a strong case for the avoidance of routine T tube drainage for hepatic injury, but the evidence for the avoidance of T tube drainage in the major blunt injury requiring resection is not clear. The use of antibiotics in patients requiring resection is also somewhat scantily dealt with, but these are minor criticisms of an otherwise excellent contribution.

The chapter by Professor R. Y. Calne puts the case for liver transplantation and carries an authority which few people have the experience to question. Perhaps the case against auxiliary liver transplantation is too strongly made. The controversy relating to the wasting of the transplanted auxiliary liver has not been resolved and there is as yet no firm evidence that specific hepatotrophic factors exist. One may be a little concerned about the use of transplantation for various forms of liver cancer, but the chapter by John Dawson makes it clear that the current therapeutic approach to malignancy within the liver leaves much to be desired. Mr Dawson makes a balanced contribution but perhaps underemphasizes the possible value of chemotherapeutic agents used early after diagnosis in the asymptomatic patient.

The remaining chapter on cirrhosis of the liver and acute hepatic failure is from Professor Terblanche's group at Cape Town and outlines the approach of this experienced team, particularly in dealing with the problem of bleeding varices as a result of portal hypertension. The chapter is perhaps less valuable to the specialist in that the approach to problem areas is somewhat superficial. For example, it is a little disappointing to see the hepatorenal syndrome referred to as a complication of operation on cirrhotic patients without further clarification.

Perhaps the most enjoyable feature of this book is the comments at the end of each chapter. In particular, Professor Walt's criticisms carry the stamp of authority and wide experience. This is a book of value to generalists and specialists alike and succeeds in its aims of bringing the atmosphere of the forum to the reader.

L. H. BLUMGART

Prostheses and Rehabilitation after Arm Amputation

L. F. Bender, Michigan. 228 × 150 mm. Pp. 179+xv, with 76 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. $12.50.

THIS little book deals with some of the problems resulting from either upper limb amputation or congenital arm deficiency, as seen in the United States. The causative factors and incidence are similar to those in the United Kingdom, viz. a high proportion being due to trauma (mostly industrial) and about 20 per cent congenital in origin, compared with 30 per cent in Britain.

It is surprising to note that out of 400 upper limb amputations seen by the author, only 9 were performed for lesions of the brachial plexus. He rightly advocates arthrodesis of the shoulder and above-elbow amputation for the complete lesion. The reviewer, however, does not agree with the recommended level of bone section given as 2½ inches above the end of the humerus. It should be at least 4½ inches otherwise the automatic elbow mechanism, used on British prostheses, cannot be incorporated.

Although there is a chapter on 'Levels of Amputation', it gives negligible guidance to surgeons concerning optimum levels. The disadvantages of long above-elbow and below-elbow stumps and of an elbow disarticulation are not stressed. The problems of fitting a wrist disarticulation are mentioned although these have been overcome in the United Kingdom.

Immediate postsurgical fitting is discussed together with the difficulties experienced. These are due mainly to the fact that the majority of the amputations are traumatic and the various receiving hospitals are not conversant with all the techniques involved. Nevertheless, when such fittings have been performed they have been quite successful. It is universally agreed that the sooner a prosthesis can be fitted the greater the chances of an amputee becoming two-handed again. Consequently, the author very rightly stresses the need for early fitting for bilateral amputees.

There is an excellent chapter on postoperative therapy and methods of performing numerous daily tasks one-handed.

The author has nothing new to offer for the relief of phantom pain although he states 'acupuncture warrants investigation'. More than two-thirds of the book are devoted to prosthetic fabrication, fitting and harnessing. Although the basic principles are similar there are major variations between the American and British techniques.

Mention is made of a variety of hands and other terminal devices including the widely accepted 'split-hook'. Credit for the myoelectric hand goes to the USSR, while the pioneer work in this field started in Britain is overlooked! There is, however, no indication of the acceptance rate among American amputees.

IAN FLETCHER

Ferguson's Surgery of the Ambulatory Patient

Edited Mark W. Wolcott, Salt Lake City, Utah. Fifth edition. 250 × 180 mm. Pp. 554+xv. Illustrated. 1974. Oxford: Blackwell Scientific Publications. £13·50.

DURING the past decade there has been a growing interest in 'day case' surgery in this country. The surgery of the ambulatory patient has advanced further in the United States than here not only because of the mutual problem of pressure on hospital beds, but because, as the Editor states in the introductory chapter, the growing cost to the individual patient in the United States 'has nearly priced the average citizen out of the health care market'.

Our ability to carry out an increasing range of surgical procedures without admitting the patient to hospital is largely due to the considerable advances in modern anaesthesia, which is discussed in the extremely informative chapter by Dr Edwin L. Rushia.

The selection of material for such a book must be extremely difficult and, by and large, the Editor is to be congratulated on the range of topics he has chosen. Not only are the usual procedures for 'minor surgery' described in detail, but there is important information dealing with the relatively minor surgical procedures which are often required for the satisfactory care of patients discharged from hospital following major surgery.

In a book with such wide coverage it is inevitable that a number of oddities will appear. To find axillary boils ('hidradenitis suppurative of axilla'!) in the same chapter separated by only a few pages from fractures of the scapula, including its rarer forms, is perhaps somewhat surprising. Although it is doubtful whether British surgeons would find it acceptable to treat in an outpatients' department malignant disease of the oral cavity, the chapter on cryosurgery by Dr Andrew Gage does open up important new vistas. The chapter on the breast has a number of surprises: can intraductal papillomas be dealt with satisfactorily in an outpatients' department, and is this the right book in which to describe in detail the technique of an operation for gynaecomastia?

In spite of these occasional excesses, the book contains a vast amount of serious practical information. The illustrations are simple and clear. A young house surgeon, casualty officer or general practitioner wishing to continue the active personal care of his patients following major surgery would do well to peruse this book and keep it on his shelf.

L. KESSEL

Reactions to Injury and Burns and Their Clinical Importance

S. Sevitt, Birmingham. 210 × 140 mm. Pp. 255 + vi. Illustrated. 1974. London: William Heinemann Medical Books. £4·25.

RECENT monographs concerning the response to injury have tended to deal with the more general metabolic features which follow injury, perhaps because this is the important feature of clinical management which has been most topical. There has therefore been a need for an approach to the subject which has taken a broader view of the systematic and general reaction of the body to injury. This is the purpose of this monograph by Dr S. Sevitt.

The first part deals with the statistics of accidental injury, the factors related to death from injury and the normal homeostatic responses, and this provides the base for the subsequent sections on the effect of injury on tissues such as the lungs, liver, kidney and central nervous system. Much of the descriptive element and the discussion revolves around severe trauma associated with shock or hypoperfusion. The chapter on endocrine responses in particular is comprehensive and is a useful review of the many changes which are found in the injured patient.

The last section details changes in coagulation, fat embolism and immunity, cellular and humoral, in the traumatized or burned patient. This is an especially useful part of the book which deals unusually with aspects of trauma not normally discussed in relation to the metabolic changes, and this adds considerably to the breadth of the topic being covered. It was, however, tantalizing to find points raised which could not be followed up in the rather brief bibliography supplied, but one must accept this in a relatively concise work such as this. This book will be of use to any doctor concerned with the management of the injured or severely ill patient.

R. G. CLARK

Surgery Annual: 1974 Vol. VI

Series editor: Lloyd M. Nyhus, Chicago, Illinois. 236 × 165 mm. Pp. 489 + xii. Illustrated. 1975. Hemel Hempstead: Prentice-Hall International. £12·95.

THIS annual review of surgery is now well established in its sixth year. The Editor has selected 31 contributors, mostly from the United States, but has included several South Africans, a Finn and Professor David Johnston, now at Bristol. The 20 chapters are widely ranging indeed; the spectrum stretches from chapters on basic topics such as metabolic aspects of shock, techniques of blood flow measurements and sickle cell disorders, through the applications of computers to patient care, paediatric anaesthesia and gastric mucosal anomalies to general surgical topics which include the management of pancreatic cancers. Under orthopaedics there are chapters on hand injuries, the surgery of rheumatoid arthritis and total knee replacement arthroplasty. Highly specialized subjects such as carbon dioxide laser surgery in laryngeal disease and intracranial infections give a fascinating account of the advances in these fields. Of particular interest are the excellent contributions by Leslie Wise on controversies in the management of so-called 'early' breast cancer, and a discussion by John Madden on the controversial topic of electrocoagulation in the treatment of cancer of the rectum, which includes useful advice on the exact technique of this method and the indications for its use.

This volume, like its predecessors, is beautifully produced and illustrated with up-to-date and copious references. Being so widely based, it will be particularly attractive to general surgeons (who are always keen to keep abreast of current work in adjacent fields) and to candidates for higher surgical degrees, rather than to our somewhat less fortunate colleagues, the 'super-specialists'.

HAROLD ELLIS

Ventilatory and Phonatory Control Systems

Edited Barry Wyke, London. 230 × 155 mm. Pp. 531 + xviii. Illustrated. 1974. London: Oxford University Press. £6.

SMALL symposia, whether they be national or international, are usually of considerable value to the participants most of whom have been selected for their special interest in the subject under discussion. Whether a much wider audience exists justifying publication of the proceedings of such meetings is largely dependent on the importance of the topic and the speed with which the papers can be printed in an acceptable manner. Unhappily, 3 years after presentation is too long even for the most original and important contributions—and this meeting was held in January 1972! Since the editor personally thanks the participants for promptness in producing their papers the blame for delay must lie with the publishers. This is sad, for although the quality of reproduction of illustrations is poor this book represents exceedingly good value for money.

Twenty-five papers were given by contributors drawn from many countries and a wide variety of disciplines, ranging from respiratory physiology to phonetics. Their collective ambition was to evaluate the current position and possible lines of future research in the related fields of ventilatory and phonatory control. Despite the vastness of this undertaking they succeeded remarkably well, and the division of the various papers into four sections assists the reader in digesting the mass of facts and figures which appear to be an integral part of each paper.

An additional bonus is the inclusion of the free discussions which followed individual communications. All show evidence of meticulous editing, whilst the addition of appropriate references suggests that some of the delay in publication may be related to this section of the book.

All who are interested in the mechanisms which control breathing, speaking and singing will find this book a valuable source of information and ideas. Whether it will still stimulate new lines of research 3 years after its original conception is more doubtful, but in view of its modest price and original integration of multidisciplinary expertise it is certainly worth buying.

D. F. N. HARRISON

The Systematic Manifestations of Inflammatory Bowel Disease

Edited William M. Lukash and Raymond B. Johnson, Bethesda, Maryland. 228 × 152 mm. Pp. 356 + xii. Illustrated. 1974. Springfield, Ill.: Charles C. Thomas. $15.50.

THIS work will be of interest to the *cognoscente* because of the surprises it contains and the occasional lacunae; it would be unwise to recommend it to those without experience. The first surprise comes early: ulcerative proctitis, it is stated, is a relatively uncommon form of inflammatory bowel disease. This is hardly the experience here; perhaps populations differ, for the book is based on a symposium of United States Army doctors. Perhaps it reflects the physician orientation which obtrudes elsewhere, for proctitis may be seen more often in surgical clinics whence patients are referred as cases of 'bleeding piles'. This orientation is dominant in the attitude to therapy, an attitude hardly aggressive in character; of this the reader becomes particularly aware in the chapter on toxic megacolon, for its whole tenor is towards conservative treatment with little appreciation that the mortality of this condition can be contained only by recognition of bowel disintegration, with appropriate surgical action, before dilatation has developed (moreover none of the four contributors to this chapter is a surgeon). Elsewhere 'joint symptoms are seldom of sufficient severity to require surgery' must be the attitude of a softline therapist rather than the activist who knows from experience that joint trouble is usually an additional factor indicating that the time for surgery has arrived.

Some of the lacunae are minor, such as the omission of Crohn's stomatitis, and, in the chapter on cutaneous manifestations, those stigmata of prolonged severe disease, the striae 'non'-gravidarum seen in relation to the extensor surfaces of knees and elbows, and the skin attenuation on the digits of those with persistent hypoproteinaemia. Perhaps these conditions have not come the authors' way (the author of the chapter on differential diagnosis states that he has never seen tuberculosis of the bowel, or has failed to recognize it).

A comprehensive chapter on radiographic features provides useful 'visual' differential diagnoses; here numerous conditions including parasitic infestations are presented, some of which would hardly spring to mind for diagnostic exclusion, but lymphoma is omitted. More importantly, the simulation of diverticulitis by Crohn's disease of the sigmoid and that of terminal ileitis by chronic appendix abscess are conspicuous by their absence. A more considerable omission is the failure to appreciate that ischaemic colitis is bound to inflammatory bowel disease if only because it can masquerade as ulcerative or Crohn's colitis. Moreover, it is not confined to the elderly and retired, but must sometimes affect more active echelons, even generals less celebrated than Eisenhower, whose case history is fully exposed in the first chapter as an exemplar of Crohn's disease.

B. N. BROOKE

Atlas of Orthopaedic Surgery. Volumes 1 and 2

L. A. Goldstein and C. Dickerson, New York. 280×215 mm. Vol. 1: pp. 524+xiv; Vol. 2: pp. 592+xiv; 1674 illustrations. 1974. London: Henry Kimpton. £41·55.

THIS beautiful production is nearly a winner, but not quite. It falls between three stools. It is not a highly technical instruction book like the AO manual on fracture treatment, it is not a vade-mecum with a comprehensive commentary like Campbell and it is not a friendly but highly personal and subjective guidebook like Couzens. Yet in so many ways it is splendid. The layout is spacious, the type clear, the paper opulent and the binding sturdy. Most of the 1674 illustrations are enormously elegant, the references at the end of each section are catholic and helpful and the index of subjects and authors at the end is clear and comprehensive.

However, there are snags. In a book of this magnitude the most obvious is lack of diversity. Often only a single procedure is described for each disorder, and when the condition is as common and controversial as recurrent anterior dislocation of the shoulder this seems surprising. The somewhat meagre general discussion which opens each section might well have been expanded to include justification of the particular operation selected. The drawings delight the eye, but not all contain the detail which would make lengthy commentary superfluous—it is a pity that some of the acres of blank space have not been employed in providing more substantial verbal support. Consistency in illustrating always the right arm and right leg shows a perceptive awareness of the trainee's problems, so it is surprising that within the space of a few pages (759–65) the lower limb lies first from right to left, then vertical and finally from left to right.

Much of this criticism is mere carping. No work could maintain throughout the high standards of some sections, such as that on scoliosis, and no first edition of so ambitious a nature could be without blemish. These two volumes will be invaluable to residents, registrars and to many established surgeons. They represent immense effort and are an enormous achievement; they may be the prelude to a brilliant second edition.

A. GRAHAM APLEY

Symposium on Management of Cleft Lip and Palate and Associated Deformities. Volume 8

Edited Nicholas G. Georgiade, North Carolina. 280×220 mm. Pp. 324+xiii, with 685 illustrations. 1974. London: Henry Kimpton. £20·20.

THIS volume records the transactions of a symposium sponsored by the Educational Foundation of the American Society of Plastic and Reconstructive Surgeons. It contains 53 monographs written by the contributors, who include representatives of all the disciplines which share the responsibility of treatment of these complex deformities. The material includes anatomy, aetiology, general management, speech pathology, otology and orthodontics besides the surgery of primary repair and secondary correction, together with a good historical review of the development of this subspeciality of plastic surgery. All the disciplines concerned will find much of general interest and something of their own special contribution.

In the realm of surgical treatment the techniques advocated understandably bear the stamp of the preference of the individual contributors, and the inexperienced might find a choice difficult to make, but the trend of current thinking comes through, and those already experienced will find valuable the suggestions of the protagonists of alternatives. The editor has done well to produce a volume with an even high standard of presentation which is unavoidably a potential difficulty in a multi-author book. The illustrations are abundant and lucid, making for easy understanding of the intricacies of operative techniques. The production of the volume is of a very high quality; in some of the chapters the bibliography could have been extended with advantage.

DAVID MATTHEWS

Cardiac Arrest and Resuscitation

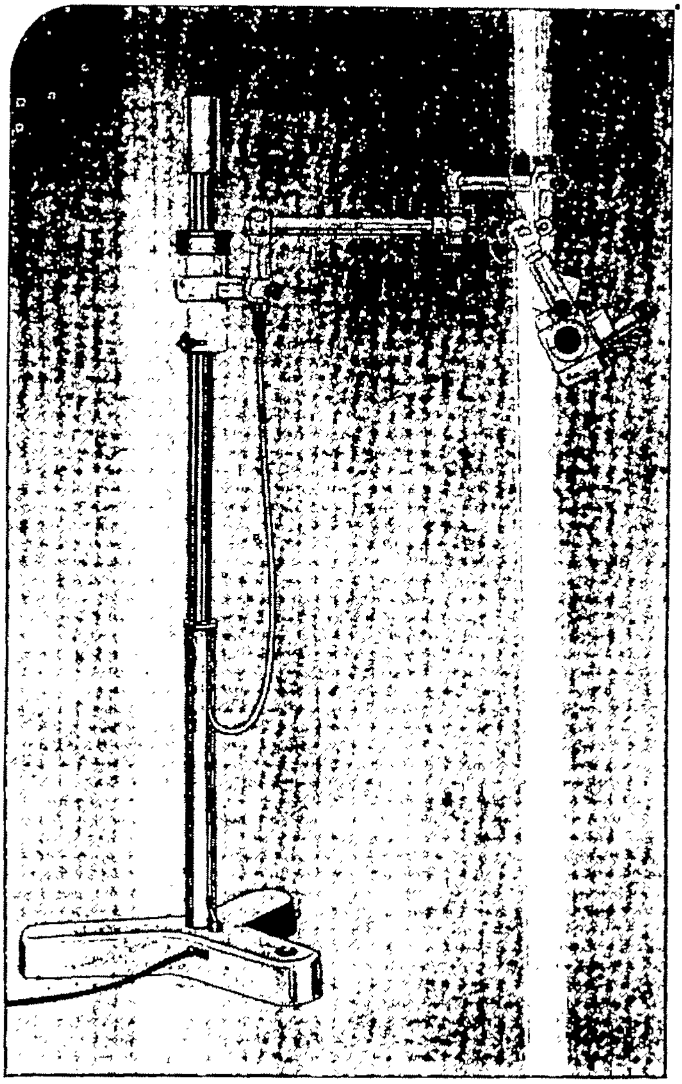
Hugh E. Stephenson, Columbia, Missouri, Fourth edition. 250×180 mm. Pp. 998+xviii, with 379 illustrations. 1974. London: Henry Kimpton. £22·55.

No improvement in life expectancy has been achieved in adult white males in the United States in this century despite medical advances. This lack of progress is to a considerable extent a consequence of the coronary epidemic which annually claims half a million lives in the United States and over 130 000 in England and Wales. Most of these deaths occur outside hospital. Drowning, electrocution, surgery, therapeutic agents, anaesthesia, etc., contribute to the total who die suddenly.

This admirable book provides a comprehensive current review of these topics, adding considerable new information since the last edition in 1969. A distinguished team of contributors from various disciplines assesses the detection and prevention of risk factors and the mechanism and pathophysiology of arrest. Resuscitation techniques are evaluated, including developments in pacing, circulatory assist by inter-aortic balloon pulsation and progress towards an effective artificial heart. Practical details are provided on equipping and training mobile resuscitation units and should encourage their hitherto sluggish development in the United Kingdom. The experience of stadium resuscitation units will interest sports medicine specialists and first aid personnel. The medicolegal aspects appertaining to the United States are dealt with in hair-raising detail and provide very sobering thoughts for a British reader.

The book provides a fine seam of reference sadly marred, however, by the frequent omission of dates in the text which renders mining the original more difficult; suggestions that the reader should refer to previous editions for references not included here are hardly likely to help those who have not managed to collect each edition. Inevitably a book by many contributors is patchy, chapters varying from excellence to a folksy anecdotal style. It is expensive (£22·55) and cumbersome. Nevertheless, it contains important material and should at least be dipped into by those likely to encounter cardiac arrest, namely all of us.

G. M. REES



SURGERY MICROSCOPE II

Another superb instrument from

CARL ZEISS JENA

This well established Surgery Microscope from VEB Carl Zeiss Jena has gained a well deserved reputation for it's reliability and all-round performance. It is extremely versatile, allowing complete freedom of movement. The working distance is 200-300 or 400mm. You'll be surprised at the competitive price of this popular microscope which incorporates optics of the highest quality. Remarkable value!

SPECIAL FEATURES INCLUDE:-

- ✻ Individually focussing eyepieces
- ✻ Rapid changing for two filters and five magnifications (5x, 8x, 12.5x, 20x, 32x)
- ✻ Observer eyepiece available
- ✻ Photographic attachments available.

Write or telephone for literature or demonstration on this instrument and others in the comprehensive VEB Carl Zeiss Jena Range.

INJURY

The British Journal of Accident Surgery

Editor, R. L. BATTEN, FRCS(Eng)

Injury provides a focal point of information for those engaged in the many fields of medicine which accident surgery involves. Contributions from all over the world provide well-organized and comprehensive coverage of every aspect of care of the injured. Original articles take up a large section of INJURY and, as accident surgery is so often concerned with the individual patient, reports of interesting and complex cases are included. To keep the reader informed of the latest progress, INJURY contains details of current research and of new drugs and medical instruments. Reviews of new books appear regularly and, of particular value in a field of medicine which often has a debt to other specializations, INJURY devotes some of its space to abstracts from a wide range of publications on related subjects.

BURNS including Thermal Injury

The Journal of the International Society for Burn Injuries

Editor, J. E. LAING, FRCS

To counter the high mortality and morbidity caused by burn injuries needs the teamwork of a wide range of specialists: treatment of the patient can involve plastic, paediatric and orthopaedic surgeons, biologists, immunologists and bacteriologists, while the rehabilitation of the patient can need the efforts of occupational therapists, physiotherapists, psychiatrists and social workers. This new journal is published to foster the exchange of information amongst all those engaged in preventing and minimizing the effects of burn injuries. BURNS is sponsored by the International Society for Burn Injuries, whose aims are to transcend national boundaries in improving the prevention and care of burns by education, research, practical advice and assistance, and the encouragement of cooperation between all countries and all specialists.

CHRONIC TONSILLITIS
successfully treated by ultrasonic therapy

Detailed information available from

V/O MEDEXPORT

31 Kakhovka, Moscow 113461, USSR. Telex 7247
Tel: 121-01-54

The LOR-1A apparatus produces mechanical vibrations of ultrasonic frequency which have a therapeutic effect on infected tonsils. Clinical tests have shown 75% success in patients treated. Advantages of the LOR-1A are its small dimensions and low weight (less than 5 kg) and its proven safety, reliability and ease of operation. Small ultrasonic generator of low operating voltage permits direct treatment to tonsils.

Charles Davis
1850-1920

Fred Geck
1856-1942

History shows that between them they made an important contribution to the improvement of catgut as a suture material. They didn't achieve the ideal, but then, their tradition was in catgut.

In 1962, the Davis and Geck research team started on a new approach, breaking with tradition. Their objective was to develop a better, natural, absorbable suture, because of the inherent unavoidable problems of catgut's basic material, animal intestines.

From this research came DEXON* sutures, formulated from the juice of grapes and other fruit. DEXON*, now proven to be the ideal natural absorbable suture.

If you are still using catgut, this could be the right time to consider a break with tradition. DEXON* sutures may take a little getting used to, but you, and your patients, will quickly see the advantages. However, if you prefer to stay with tradition, Davis and Geck catgut is still the best available.

Thanks to the years of research by Mr. Davis and Mr. Geck.

ACM endoscopes leave nothing to the imagination

ost surgeons today recognise the superiority of endoscopy as a ans of confirming diagnoses of colon diseases. It can be quicker d easier than laparotomy, and is also less traumatic for patients and kes fewer demands on hospital facilities.

The premier instrument for colonic investigations is the ACM F9L oscope. Advanced features include 12X magnification and a sharp, de angle circular image three times larger than competitive trument's.

With it a surgeon can clearly view as far as the caecum, take biopsy ecimens and perform polypectomies. After surprisingly little ctice, coloscopy can be most rewarding. And the ACM coloscope xceptionally easy to use – a single, one-handed joystick controls poly-directional tip.

There's a shorter version, too, the F9S which will reach to the nsverse colon and beyond. For the experienced coloscopist there's the dual channel F9A, a major operative, as well as diagnostic instrument.

To find out more, please use the coupon. Or write or telephone.

The new evidence for Trasylol in the treatment of acute pancreatitis

Prospective double-blind trial in 105 patients over a five year period shows Trasylol to significantly reduce mortality and morbidity in acute pancreatitis.[1]

Course of illness		
Mild	● 30 patients (56·6%)	○ 22 patients (42·3%)
moderate	● 13 patients (24·5%)	○ 9 patients (17·3%)
severe	● 6 patients (11·3%)	○ 8 patients (15·4%)
DIED	● 4 patients (7·5%)	○ 13 patients (25·0%)

● Trasylol group (53)
○ placebo group (52)

'Trasylol must therefore be regarded as a drug which is beneficial in the treatment of acute pancreatitis.'[1]

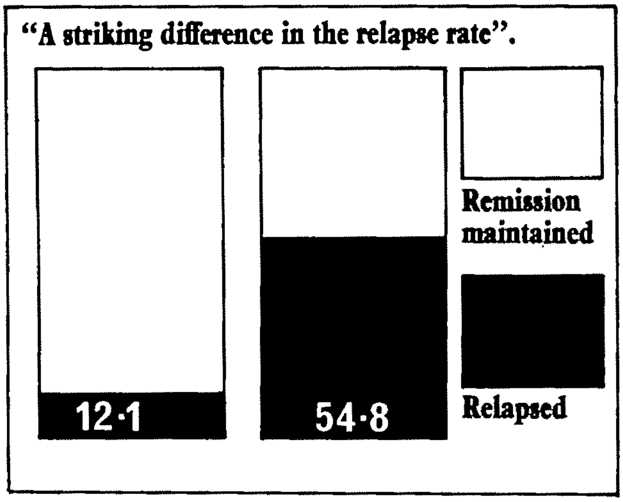
“It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects”.[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford, are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be totally ineffective in reducing the number of recurrences of ulcerative colitis.

“Fortunately, Sulphasalazine tablets, 0.5 grams, 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely, since we do not know when, if ever, it can be safely stopped”.[4]



“The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine”.[1] (Salazopyrin).

Salazopyrin (sulphasalazine) is available as the plain 0.5 g. tablet, 0.5 g. EN-tab and as an 0.5 g. suppository. Literature and detailed information on Salazopyrin are available on request.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 61. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended. Leaflets giving further instructions are available on request.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

PRESENTATION OF STATISTICS

Authors are reminded that with the frequent use of statistical analysis in biological writing of all kinds it is desirable that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinical trials the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached.

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are more than two authors these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

Surgical complications of implanting pacemakers

HAROLD SIDDONS AND K. NOWAK*

SUMMARY

An analysis of the complications of implanting pacemakers at St George's Hospital between 1967 and 1973 highlights the difficulties of implanting foreign bodies. During this 7 years 1543 pacemakers were implanted in 779 adults. In 91 patients there were 118 implants with surgical complications, most of them due to a pressure necrosis or local infection; 3 septicaemias occurred. The various complications are classified and related to technique of implantation. Methods of management of the complications are presented.

As an Appendix the operative techniques of first and subsequent implantations are outlined.

THROUGHOUT the period of study endocardial (transvenous) electrodes have been used as the first method of pacing. Only 41 of the implantations have been with epicardial electrodes. Most of the pacemakers have been the British-made Devices models, but a few products of eight other manufacturers have also been used. The average life of the Devices pacemakers was between 2 and 3 years.

The optimum technique of implantation has been developed over the 7 years, and skin necrosis over the implant has been attributed in many instances to failure to comply with basic surgical principles, the importance of which became evident as experience grew. Operative procedure as now recommended is described in the Appendix.

The site most frequently chosen was the lateral chest wall behind the pectoral fold, referred to throughout this paper as the axilla, but the anterior chest wall was also used, particularly in women. When using electrodes placed on the heart at operation the pacemaker was put behind the rectus in its sheath, and this site was occasionally used with endocardial electrodes.

Owing to the possible risk of ventricular fibrillation, when an endocardial wire provides a low impedance path to the heart, diathermy has not been used in this series. Some of the patients have been on anticoagulant therapy; there has not been undue bleeding when the prothrombin time has not been excessive. The pacemaker pockets have not been drained.

Classification of complications

Of the 1543 implantations, 118 (7·6 per cent) required some form of revision due to wound complications. (The minimum period of follow-up was 12 months.) These complications can be divided (*Table I*) into: (1) a group of 39 which appeared to be inflammatory, (2) a group of 64 in which the pacemaker or electrode produced skin necrosis and (3) 15 miscellaneous complications.

Table I: CLASSIFICATION OF SURGICAL COMPLICATIONS

Group	No. of complications	Total	% of 1543 implantations
1. Inflammatory		39	2·5
Wound infection			
'Early'	25		
'Sinus'	11		
Septicaemia	3		
2. Skin necrosis		64	4·1
Over pacemaker	52		
Over wire	12		
3. Miscellaneous		15	1·0
Pain	5		
Wound dehiscence	5		
Pacemaker rotation	2		
Haematoma	2		
Muscle twitch	1		
Total		118	7·6

Group 1

These patients presented in three different ways: (*a*) with the signs and symptoms characteristic of inflammation ('early', 25 cases); (*b*) by developing a sinus in the scar ('sinus', 11 cases) and (*c*) with septicaemia (3 cases). The time elapsing between implantation and revision is shown in *Fig.* 1.

The 25 patients with signs of inflammation are considered to have been contaminated with bacteria at the time of operation. Infection was evident within 4 weeks in 17 cases. In 8 the implant did not require surgical attention for between 1 and 6 months.

LIBRARY

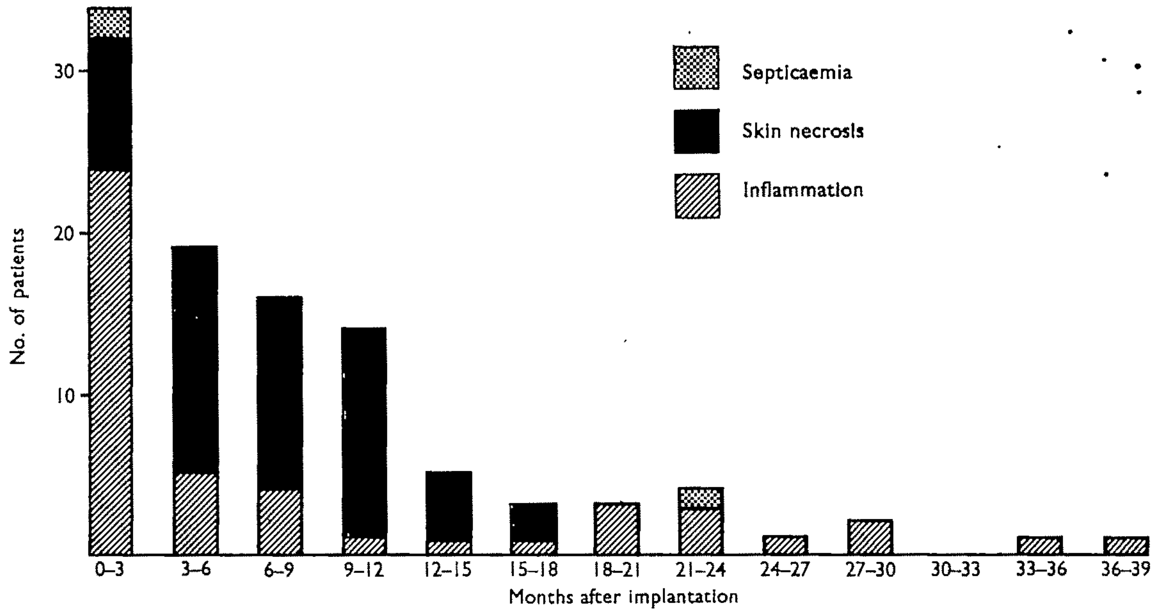

Fig. 1. Period between implantation and revision.

Wound cultures were rarely taken before the skin barrier had been broken by discharge. Early swabs were nearly always sterile, and the use of antibiotics may account for this. After a few days the commonest organism grown was *Staphylococcus albus*. Although this may have been a contaminant there is some evidence that in the presence of a foreign body it may be a significant organism (Wilson and Stuart, 1965).

The sinus with which 11 patients presented was always in the scar. This distinguished them from the 64 patients in group 2 in whom the skin gave way over the most prominent part of the pacemaker or wire. It is not certain that this type of reaction was due to a bacterial infection. In the few in whom fluid was obtained from the pacemaker pocket before a sinus to the surface had allowed bacteria to enter, the exudate was sterile. It is possible that the reaction was to the material covering the pacemaker, though it was not confined to any particular covering material.

It is instructive to relate the percentage of cases showing inflammatory complications (subgroups 1*a* and *b*) to the surgical facilities available at the time of implantation. Throughout the series all the operations for placing electrodes on the heart surface have been done in the operating theatre. However, for the first 21 months of the period surveyed the operations involving placing endocardial electrodes were carried out under the image intensifier in the X-ray department which was not specially designed for sterile procedures. For the remaining 5½ years the procedures were carried out in a specially designed small operating room. The percentage of inflammatory complications (both early and late) before the change was 3·7 per cent (7 of 190) and after the change 2·3 per cent (31 of 1353). These figures do not show a statistically significant difference.

The use of the operating room can be divided into two periods. At first all the procedures were covered with prophylactic ampicillin 1 g daily and cloxacillin 1 g daily for 5 days. Later, for a period of 18 months antibiotic cover was only used if there was a special indication, such as previous infection, operative contamination or diabetes. In this period antibiotics were used in less than 5 per cent of all cases. The rate of inflammatory complications when using the operating room with antibiotic cover for all patients was 2·8 per cent (25 of 890), and since reducing the use of antibiotics to only in a few selected cases it was 1·3 per cent (6 of 463).

The incidence of inflammatory complications in subgroups 1*a* and *b* has clearly been linked with repeated operations at the same site, and almost half (17 of 36) the inflammatory incidents had been preceded by wound infection or skin necrosis with previous implants. The incidence of these complications following 726 first implantations was 5·4 per cent and following 817 subsequent implantations 7·5 per cent.

Two other factors appeared to influence the incidence of wound inflammation: the use of epicardial electrodes and the abdominal site for pacemaker implantation (*Table II*). The comparisons are not strictly valid as the epicardial electrodes were used almost exclusively in patients who had previously been paced endocardially and had developed complications such as repeated electrode displacement or a rise in the endocardial threshold required for effective pacing.

There was no significant difference in the incidence of skin necrosis in those with axillary-sited pacemakers (39 ulcerated in 1130 = 3·5 per cent) compared with those with pacemakers sited anteriorly (8 ulcerated in 326 = 4·1 per cent).

The 3 patients in group 1*c* developed septicaemia. In 2 there was a clear explanation of the cause. In one of them a small abscess developed at the vein entry

Table II: COMPLICATIONS RELATED TO ELECTRODE AND IMPLANT SITE

Electrode and pacemaker site	No. of implants	Inflamed	Skin necrosis	Other	Total complications
Endocardial					
Chest wall	1447	27	56	13	96
Abdominal wall	53	6	5	0	11
Epicardial					
Chest wall	9	1	0	0	1
Abdominal wall	34	5	3	2	10
Total	1543	39	64	15	118

site in the neck, and the septicaemia was evident within 18 days of implantation. The second patient had had prolonged treatment with the electrode wire coming through the skin to an external pacemaker before implantation. The third patient was found at autopsy to have undiagnosed aortic stenosis with vegetations on the valve. The implant had been in place for nearly 2 years. Ten blood cultures during his terminal pyrexial illness were negative, but *Staph. albus* and α-haemolytic streptococcus (viridans type) were grown from the valve vegetations. The incident is recorded for completeness, but it is believed that the septicaemia was not related to the pacemaker system.

Group 2

More common than the inflammatory reaction to bacterial contamination or the chemical nature of the pacemaker is its *mechanical* effect. Pressure necrosis of the overlying tissue and eventually of the skin has proved a serious problem. There is usually no difficulty in determining that the skin is giving way as a result of a mechanical effect rather than an inflammatory reaction. Over a period of weeks the tissue covering the pacemaker thins, takes on a dusky red hue and then necroses. Once the skin has given way, bacterial invasion complicates the picture, though gross suppuration may not follow for weeks or months. The site of the lesion is over the most prominent part of the pacemaker and rarely at the site of the incision, which is invariably the site with inflammatory sinuses.

Such mechanical necrosis developed in 64 of the 1543 implantations. In many of these it was possible to forestall bacterial infection by resiting the pacemaker before the skin had completely given way.

Group 3

These 15 miscellaneous cases consist of: 5 in which pain over the pacemaker necessitated resiting; 5 in whom a wound dehiscence occurred, possibly as a result of taking out the sutures too soon; 2 with haematomas which were so large that they necessitated evacuation; 2 in whom the patient rotated the pacemaker, pulling on the electrodes and endangering their position; 1 with twitching due to local muscle stimulation.

Management of complications

Haematomas and other effusions

These have only been aspirated if they threatened to disrupt the suture line and discharge. Even if aspiration is expertly performed, there is a subsequent tendency for fluid to seep out and this may lead to ascending infection. If infection is thought to be the cause of a pocket effusion, aspiration is indicated.

Infection

At the first sign of infection a combination of an antibiotic suitable for prevalent staphylococci and a wider spectrum antibiotic was given systemically. A few infective incidents subsided with this régime. Once purulent material, whether sterile on culture or not, was draining, this treatment proved disappointing. Temporary improvement was almost always followed later by a discharging sinus, even with prolonged antibiotic treatment. Early in our experience it became clear that the prolonged treatment could be avoided if it was accepted at an early stage that the pacemaker should be removed and a new pacemaker implanted at a new site. The electrode was chemically sterilized *in situ* and reused, without recurrence of infection in 8 of 10 cases. At operation care was taken to separate the new from the old site, which was drained for 24 hours. Perhaps the safest method is to use a new electrode on the contralateral side, though even this has been followed by infection on occasion.

In patients with grossly infected wounds the pacemaker was taken out, the wire arranged so that it had a long subcutaneous track before entering the vein and pacing was continued with an external pacemaker until the suppuration had subsided. Thorough attempts were made to clear the skin of pathogenic bacteria by repeated skin preparation before implanting an alternative pacing system.

Septicaemia

In both the patients in whom septicaemia was diagnosed the infection was controlled by antibiotics. The original electrodes were changed for others using different veins. This proved satisfactory in one, but septicaemia recurred in the other who was then paced with an epicardial electrode. The third patient was not under our care for his terminal illness. Septicaemia was not diagnosed until after death.

Skin necrosis

Provided that the skin had not completely given way and there was no infection, the pacemaker or a replacement was reimplanted in a new site, taking all possible steps to provide adequate soft tissue cover. If the pouch had been made too superficial the new site was prepared deep to the walls of the old pouch, which themselves provided a good layer of protective tissue interposed between the outer surface of the pacemaker and the skin. Sutures were used to separate the new pouch from the old pocket, which was drained for 24 hours through a separate stab incision. Sometimes when the wire protruded it was possible to reroute it along a deeper course. Occasionally, silk fixation stitches appeared to be the cause of a sinus and removal of the stitch with little other revision resulted in prompt and permanent healing.

Discussion

The *incidence* of surgical complications is similar in this series to that reported by others. However, few of these reports have related the complication rate to technique, and the length and completeness of follow-up are not always indicated.

Analysing the figures from 21 authors (Edhag and Lagergren, 1969; Witte et al., 1969; Fishman et al., 1970; Goldman et al., 1970; Seling and Sykosch, 1970; Shepard et al., 1971; Dixon et al., 1972; Imparato and Kim, 1972; Conklin et al., 1973; Homan van der Heide et al., 1973; Kantrowicz et al., 1973; Linschoten et al., 1973; McLaughlin et al., 1973; Mascarenhas and Center, 1973; Seremetis et al., 1973; Torresani et al., 1973; Codini et al., 1974; Sowton et al., 1974; Uhrenholdt et al., 1974; Williams et al., 1974), each of whom have reported 100–800 implantations in the past 5 years, the mean figure for surgical complications is 5·1 per cent in 7205 implants. (This incidence may be an underestimate as not all the reports indicated whether they included skin necrosis with infection.) The lowest infection rates were recorded by Linschoten et al. (1973), with 277 primary implants using endocardial electrodes without infection and only 2 infections in 308 replacements, and by Conklin et al. (1973) with 2 in 403 implantations.

In the present series the overall *inflammation* incidence (excluding skin necrosis) was 2·5 per cent and with the technique currently used 1·3 per cent. These figures, which certainly show no greater infection rate without antibiotics, justify the policy of not using prophylactic antibiotics routinely. If antibiotics do confer a significant reduction of the infection rate this series is probably large enough to have shown it. The practical disadvantages of incurring the risk of drug sensitivity reactions must be considered. In the period when cloxacillin and ampicillin were used routinely diarrhoea and other intestinal symptoms were more common than without them. Hospital discharge frequently had to be delayed for this reason.

The results of this series also indicate that haematoma formation with its added risk of infection can be kept at an acceptable rate without draining the pacemaker pocket or using diathermy.

The incidence of *skin necrosis* in the present series of 4·1 per cent is much more disturbing and an analysis has been carried out to see if the records clearly relate skin necrosis to any particular step in technique. It was concluded that details of technique are of relevance and that often subsequent skin ulceration could be attributed to failure to adhere to basic surgical principles. The implantations in this series were done by a large number of surgeons and physicians of differing experience. Moreover, the importance of some points in technique, particularly when reimplanting after previous complications, was not appreciated early in the series. The results relate not specifically to the technique recommended, but to the methods whilst details of technique were being evolved.

Skin necrosis is more common in thin (and elderly) patients but occurs also when the subcutaneous tissues are lax and the pacemaker does not become firmly fixed. The incidence of this complication depends on the shape, size and weight of the pacemaker, and also on the site of implantation. Over the past 14 years manufacturers have done much to improve pacemakers by rounding off sharp corners, but they remain large and heavy foreign bodies. In 12 of the 64 skin necrosis incidents it was the wire and not the pacemaker which protruded. Early in this series the vein most often used was the external jugular, and occasionally erosion of the wire to the skin surface in the neck resulted. The use of the deeper cephalic vein has reduced the incidence of wire ulceration, but it can occur when a loop of wire is left close to the surface.

Parsonnet (1972) has stated that skin necrosis is ten times as common following reimplantations than following the initial implant. Homan van der Heide et al. (1973) reported an incidence of infection of 2·2 per cent of 268 first implantations and 6·0 per cent of 547 subsequent implantations. The figures of Kennelly et al. (1974) are 1 per cent of 196 first implantations and 4 per cent of 204 subsequent implantations. The figures reported here for infection and skin necrosis are 5·4 per cent of 726 first implantations and 7·5 per cent of 817 subsequent implantations.

Septicaemia is a recognized risk of long term intravenous pacing if the electrode traverses the skin barrier to an external pacemaker. With implanted pacemakers the risk of skin organisms travelling along the wire track to the bloodstream is eliminated. In 2 patients there was an obvious explanation for bloodstream bacterial invasion. The third patient had aortic valve disease and the bacterial endocarditis did not appear to be related to pacing.

It is interesting to note that a high rate of septicaemia (4 in 260) was recorded by Edhag and Lagergren (1969) when using a technique which involved leaving the pacemaker outside the body for a few weeks before implantation.

Twenty-one patients with septicaemia have been reported in the literature. In at least 6 of these there was local sepsis at the implant site or skin erosion (Imparato and Kim, 1972; Seremetis et al., 1973; Jablonka et al., 1974; Sedeghat, 1974). In others the only lesions to explain bacteraemia were a paronychia (Codini et al., 1974), a chest infection 2½ months after implantation (Waisser et al., 1972) and a sacral decubitus ulcer (Schwartz and Pervez, 1971). In the remainder clinical details on this point were not given (Bergovich and Fenig, 1970; Fishman et al., 1970; Torresani et al., 1973; Radford and Julian, 1974).

An analysis of a number of reports on the *management* of *infected pacemaker* pockets shows that treatment with parenteral antibiotics will not usually sterilize the pocket without resiting the pacemaker (Firor et al., 1968; Fishman et al., 1970; Seling and Sykosch, 1970; Dixon et al., 1972; Furman et al., 1973; Linschoten et al., 1973; Codini et al., 1974). If the pacemaker is not to be moved the most successful treatment appears to be frequent local irrigation with neomycin or kanamycin. Furman et al. (1973) reported success in 9 out of 13 infected pockets treated in this way. The present authors have also had success with this method, but find that it is quicker to make a new pocket, using a new electrode if there is heavy contamination.

Appendix

Procedure for pacemaker implantation

Pacemaker site: It is assumed that the electrode has been satisfactorily placed using the cephalic vein or, alternatively, a jugular vein. The axilla is the best site for the pacemaker. It may, however, prove unsuitable in very thin patients, particularly when there is no laxity or freedom of movement of skin over the ribs. It is also unsuitable if a particularly thick pacemaker is to be used and in relatively small patients. If the pacemaker is placed very high in the axilla it interferes with arm function and is uncomfortable, but most pacemakers lie comfortably a little lower behind the pectoral fold. (The Devices pacemakers which are 25 mm thick are not too large for this site in most patients. Lithium-celled units are considerably thinner.)

The next choice of site is on the pectoral muscle anteriorly, which is the position used most frequently in the USA. Cosmetically, this site is unsatisfactory in men, but in women the implant is hidden behind the breast. The pacemaker should be implanted deep to the fascia ensheathing the pectoralis major. If it is placed outside this fascia skin necrosis is liable to occur, even in women with ample space behind the breast, as the pacemaker may move in the lax tissues. Some men have had pacemakers placed both low in the axilla and on the anterior chest wall on separate occasions. A large proportion of these men find the axillary site more comfortable.

With epicardial electrodes the abdominal wall is the most convenient implant site. Pacemakers placed within the rectus sheath behind the rectus are stable and well protected, but their depth necessitates a more disturbing operation when they are replaced. If they are placed subcutaneously they require fixation to the deeper layer to prevent migration.

The side to be chosen is determined by the preference for placing the transvenous electrode. The majority in this series have been right-sided.

Preparation: The patient lies prone on a sterile drape covering a plastic foam sheet with a single pillow for the head which is turned away from the site of operation. The elbow is placed a few inches from the side so that the arm forms a triangle with the chest wall, giving good access to the axilla. Great care must be taken to keep the surgical drapes in place. The area is irregular in shape and so is unsuitable for adhesive plastic covers.

Anaesthesia: Local anaesthesia is preferred in psychologically suitable patients, and hospital stay is minimized by avoiding a general anaesthetic.

The incision: The incision used for introducing the electrode into the cephalic vein should not be extended downwards for the pacemaker's implantation as it is too remote from the best pocket site and vertical incisions in this area give puckered scars. A separate horizontal incision over the anterior aspect of the pectoralis major is preferred. This muscle is retracted medially and a pocket developed behind it on the lateral chest wall between the pectoralis major and the latissimus dorsi.

This incision allows comfortable access to the preselected pacemaker site, and makes the creation of the correct-sized pocket easy; bleeding vessels are easily detectable and the pacemaker can be accurately placed behind the pectoral fold. Some authors advocate a single incision for both electrode and pacemaker implantation. With the implant site advocated here a single incision would not offer the advantages mentioned above.

Depth and size of the pocket: It is essential that the pocket be made close to the muscle so that as much fascia and subcutaneous tissue as possible lies between the pacemaker and the skin. The pocket is developed by blunt dissection with the fingers or the back of the blades of scissors. By this means the correct anatomical plane is not transgressed and there is minimal bleeding. Too big a pocket can allow the pacemaker to rotate, which can twist the electrode wire, damaging it, and even avulse it from contact within the ventricle.

Haemostasis: All bleeding points are tied with catgut. There is some risk in the use of diathermy when an electrode has been placed in contact with the ventricular endocardium, as it provides a low resistance electrical pathway to the heart and could produce ventricular fibrillation. Prolonged swab pressure controls the tiny bleeding vessels, which in other circumstances would be coagulated with diathermy. For this reason the pocket is made early in the operation and packed with swabs whilst the pacemaker is attached to the electrode.

Measuring threshold and R wave amplitude: The technique of attaching the electrode wire to the pacemaker varies with each pacemaker model and instructions are issued with the instrument. The threshold required to pace is checked immediately before the attachment is made. This is done by connecting two sterilized wires from a separate portable pacemaker with voltage (or amperage) control. The peak-to-peak QRS is also measured using the electrode as an intracardiac ECG lead. It is not necessary to measure impedance.

Placing the pacemaker: In placing the pacemaker, attention must be paid to the site of any protuberance such as the terminal of the electrode. This is best situated behind the lateral fold of the pectoral muscle to protect it from the skin. In individuals in whom subcutaneous tissue is either very sparse or very lax there may be less risk of skin necrosis if the pacemaker is enclosed in a Dacron mesh bag as described by Parsonnet (1972).

Pacemakers with one metal surface as the indifferent electrode must be put in with this surface turned away from muscle or twitching may result. (If the operation is performed under general anaesthesia with relaxants, such twitching may be obscured.)

Spare wire should be placed deep to the pacemaker where it is out of the way of subsequent incisions to change the pacemaker. If the pocket is not firmly closed with soft tissue the wire tends to spring out and may erode through the skin.

Wound closure: The pectoralis major muscle, when released from retraction, forms a good barrier between the implant and the incision. Good soft tissue closure is essential, providing a barrier between the foreign body and the skin. The interrupted skin sutures are removed when healing is seen to be firm and not on any specific day. Healing in elderly patients requiring pacemakers may be very slow, and wounds may break down after removal of stitches even if this is delayed for more than a week.

Drainage: Drainage of pacemaker pockets is not advised on the grounds that even if the drain is small and is removed within 24 hours the track may allow skin bacteria to enter the implant pocket.

Antibiotics: Prophylactic antibiotics are not used routinely. However, patients at special risk are treated with ampicillin 250 mg q.i.d. and flucloxacillin 250 mg q.i.d. by mouth, starting before operation and continuing for at least 5 days. Previous implant sepsis, any potentially septic skin lesion, phlebitis from an intravenous arm electrode or catheters, excessive bleeding and diabetes have all been regarded as indications for the use of antibiotics.

Procedure for changing the pacemaker

This operation, though very simple in principle, can be technically tedious and time-consuming. In the hands of the impatient or unskilled the insulation on the electrode can be easily damaged, and adequate soft tissue closure between the implant and the skin may not always be achieved.

Local anaesthesia is used, and provided that the previous incision has been properly placed and is not overlying the pacemaker, it is used again, excising the scar. A preoperative X-ray to show the course of the wire is valuable, and before cutting tissue in the vicinity of the wire careful fingertip palpation is essential. An opening movement of scissors is useful in exposing the wire without damaging it. The initial aim is to cut down on to the upper surface of the pacemaker and then to open the capsule over the upper surface sufficiently to be able to squeeze or hook the pacemaker out. In order to achieve this it is often necessary to enlarge the pocket. Incisions of the capsule for this purpose must be made on its deep surface to avoid the possibility of thinning the layer of tissue between implant and skin.

The method of disconnecting and reconnecting to a replacement pacemaker differs with various pacemaker models and is described by the manufacturers in pamphlets supplied with the instruments. It is important to measure the threshold required for pacing at each change of unit. Care must be taken not to pull on the electrode; it has occasionally been displaced from contact with the right ventricle in this way. Closure of soft tissue between the implant and the skin incision is as important with each change of pacemaker as with the initial implant.

The efficiency of surgical masks of varying design and composition

LOUIS B. QUESNEL*

SUMMARY

Five different types of surgical mask of varying design and composition of natural and synthetic fibres were tested for their efficiency in vivo by means of a special test chamber. Contaminated particles escaping through or around the mask during speech by the wearer could be collected and sized. Analysis of the data showed that the gross efficiency of all the masks was high, but that some masks were distinctly better at small particle 'filtration' than others. There was a significant difference in efficiency between the best and worst masks. The best masks contained more fabric, were softer and were pleated, while the worst were stiffer, smaller and not pleated. Reusable cotton fabric masks were as effective as synthetic fabric masks when made to a good design.

ALTHOUGH the use of surgical masks has become routine in many clinical situations there persists a wide variety of opinions about their usefulness. Hirshfield and Laube (1941), summarizing the reports from twenty-one papers, recorded opinions ranging from a firm belief in their efficacy to denials of their usefulness in helping to prevent infection. One of the obvious reasons for the controversy is the difficulty of obtaining accurate assessments of mask efficiency, and a wide variety of techniques has been used in attempts to evaluate the effectiveness of different masks.

As early as 1935 Paine, in performing tests with masks made from natural fibres such as silk and cotton gauze, recognized the importance of particle size and found that 'high momentum droplets' could be effectively arrested by several layers of fine gauze. Mask efficiency actually increased with prolonged use. His test system involved a painted plaster cast of a face, through which were bored three holes representing the nares and partly open mouth. Into the back of the cast was fitted the wide end of a funnel, the narrow end being joined to an atomizer spray charged with a broth culture of *Micrococcus lysodeikticus*.

Shooter et al. (1959) tested one gauze (filtration) mask and two paper (deflection) masks and concluded that the three masks 'would fulfil their main purpose in protecting the patient's wound from many of the bacteria in the surgeon's mouth when the latter talked'. With deflection type masks it seemed 'probable that deflected expired air will inevitably carry some of the shed bacteria behind the head'. Their test system involved the use of 129 volunteers in a sitting position with the head isolated in a 'tent' through which a horizontal air flow was maintained. Organisms were collected on 20 Petri plates distributed in different locations on the floor of the tent chamber. From a variety of tests using exposed plate and slit sample techniques Thomas (1961) concluded that cotton gauze masks were much more efficient than paper masks in preventing the dispersal of 'small droplets and droplet nuclei'. Laundering of cotton masks increased their efficiency as filters.

Greene and Vesley (1962) designed a chamber which enabled them to test the efficiency of surgical masks under simulated *in vivo* conditions, using an Andersen (1958) cascade sampler. They found that a gauze and flannel mask was over 99·6 per cent efficient in blocking particles of diameter greater than 4 μm and 96·7 per cent efficient for particles under 4 μm.

Madsen and Madsen (1967) used a test chamber the same as that designed by Greene and Vesley (1962) to evaluate the efficiency of four different types of mask: a polypropylene-fibre mask, a polyester-rayon mask, a glass-fibre mask and a cellulose-fibre mask. Instead of the masks being worn by a human subject they were fixed to a dummy head made to average human dimensions (Churchill and Truett, 1957). To simulate sneezing or coughing a nebulizer controlled by an electronic timer was fitted inside the manikin head. A spore suspension of *Bacillus stearothermophilus* was used as the test organism. They obtained overall efficiencies of 98·8 and 98·4 per cent for the polypropylene and polyester-rayon masks respectively, with 97·3 per cent for the glass-fibre mask and 92·7 per cent for the paper mask.

There is at present a wide variety of surgical masks available in several different designs, manufactured from a variety of natural and synthetic fibres. Equally, many different claims have been made as to their likely efficiency in preventing cross-infection from wearer to patient. We decided to compare the performance of a selection of these by an *in vivo* method based on the procedure used by Greene and Vesley (1962).

Materials and methods

Sampling chamber

A chamber similar to that of Greene and Vesley's (1962) was constructed. It was made mainly from $\frac{3}{16}$-in plywood and $1\frac{1}{2}$-in angle iron (*Fig.* 1). The main box structure was 5 ft × 16-in × 16 in mounted vertically, of which the upper 4 ft was of square section, while the lower 1 ft tapered pyramidally to a 4-in square block of hardwood at the base. In the centre of the latter was fixed a piece of copper pipe of internal diameter

---

* Department of Bacteriology and Virology, University of Manchester, Manchester M14 9PT.

1 in. To this, externally, the Andersen sampler was linked by means of a piece of rubber tubing of similar internal diameter and about 5 in in length.

The top of the chamber had a square, lipped hole into which was fitted, exactly, a 10-in Vokes Super Vee Fibreglass Air Filter Panel No. E. 70802/1. The filter was seated on a foam plastic gasket to give an airtight seal. This type of filter has an efficiency of over 98·5 per cent for particles down to 6·0 μm in diameter and about 90 per cent for particles down to 1 μm.

One panel of the 'box' was divided at a point 1 ft from the top, and the 16 × 12-in panel formed was made to slide up and down in close-fitting grooves provided in the frame. The bottom of this panel and the top of the adjoining panel was cut out to form between them an eliptical hole about 6½ × 5½ in. This hole was surrounded on either half by a ¾-in thick plastic foam collar to leave a final hole of 4½ × 4 in which formed a snug fit around the neck of the subject when his head was inserted in the chamber and the sliding panel drawn down. The wall of the chamber opposite the 'head-port' was made entirely of clear Perspex to enable the subject to read a stopwatch placed on a bench outside the chamber and to prevent a feeling of claustrophobia.

The total volume of the chamber was 7·886 ft^3, of which 0·776 ft^3 was the volume enclosed by the pyramidal lower portion of the chamber. The volume from the line of entry of the head to the base of the chamber was 6·106 ft^3.

Test procedure

The procedure used was based on that used by Greene and Vesley (1962), but was not the same as we found it impossible to generate the large numbers of organisms which they claimed to be produced by uttering the words 'sing and chew' six times. Instead these trials required that the word 'chew' be repeated a total of 120 times during the space of 4 minutes. The exact procedure used was as follows:

1. Exactly 30 minutes before the time at which the masked subject was to insert his head into the test chamber, the test mask was fixed in place in the normal wearer's position. This was taken as zero time for the whole sequence.
2. At 10 minutes the chamber was flushed by running the sampler pump and drawing the air through for 5 minutes. During the whole of this period (and in fact from the day before) the head-port was covered by a cardboard plate sealed to the walls of the chamber by adhesive tape.
3. At 20 minutes the chamber was extracted for a further 5 minutes, this time with the sampler loaded with 6, 5 per cent blood-agar plates. This yielded the background count (column *a* of *Table 1*).
4. At 30 minutes less 15 seconds the head-port cover was removed, the sliding panel raised and the subject's head inserted into the chamber; the panel was closed to form a snug fit around the subject's neck.
5. At 30 minutes the sampler (loaded with 6 fresh 5 per cent blood-agar plates) was switched on, and at the same time the subject began to speak the word 'chew' at 1-second intervals for 5 seconds followed by a 5-second rest, alternating for 4 minutes (i.e. 30 enunciations per minute for 4 minutes = 120 words).
6. After the 4-minute speech sequence the subject remained mute until the total sampling time of 5 minutes had elapsed. The sampler was then switched

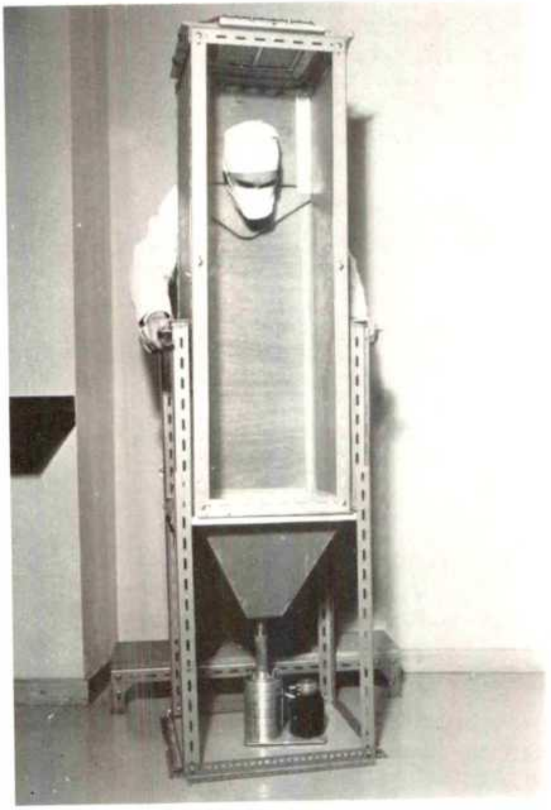

Fig. 1. The experimental chamber showing, at the top, the fibre-glass filter, the foam collar, the clear Perspex front panel and the Andersen sampler.

Table 1: COLONY COUNTS OBTAINED AT EACH SAMPLING TIME OF THE MASK TRIALS

Mask type	*a* Background	*b* Masked	*c* Post-masked	*d* Unmasked	*e* % Leak *b* of *d*	*f* % Leak *b* + *c* of *d*
Aseptex	6	91	103	2614	3·48	7·42
Cestra	22	62	101	4949	1·25	3·29
Surgine	23	109	202	8956	1·21	3·47
Filtermask	17	156	188	3747	4·16	9·18
Filtron	11	65	160	5215	1·24	4·21

Each count figure recorded represents the total colony count for four experimental trials off, the plates removed for incubation (column *b* of *Table I*) and a new set of plates loaded.

7. The subject removed his head, the head-port was sealed as before and at 40 minutes a further sample was withdrawn from the chamber, the plates removed and the sampler reloaded. These plates yielded the background count given in column *c* of *Table I.* There is no reference to such a count having been made by Greene and Vesley (1962).

8. At 48 minutes the cardboard cover was removed from the head-port and the subject reinserted his head, but this time unmasked, and procedures 5 and 6 were repeated as exactly as possible as before. This yielded the 'unmasked' counts recorded in column *d* of *Table I.*

9. At the end of the 5-minute unmasked sampling period the headport was again sealed.

Only one such mask trial was made on each day and blood-agar plates were poured freshly each day. They consisted of a bottom layer of Oxoid blood-agar base and a top layer of the same agar but containing 5 per cent defibrinated horse blood. The total volume in each plate was exactly 27 ml as required in the instructions for use of the Andersen sampler. Incubation was carried out at 37 °C for 24 hours.

Surgical masks

The masks tested were:

1. Aseptex mask No. 1800 (3M Company, Medical Products Division). This is a 'rigid' cup-shaped mask of bonded polyester and rayon fibres held in place by an elastic band.
2. Cestra mask (Robinsons of Chesterfield) made from four-ply cotton muslin. The entire batch of these masks was subjected once to the normal hospital laundry routine for articles of this type at the Manchester Royal Infirmary. They were steam pressed and packed in 'sterilization pack' paper bags, but were not autoclaved.
3. Surgine (Johnson & Johnson Ltd). Mask of three-ply construction, outer layers bonded rayon, inner glass fibre; three pleats.
4. Filtermask E-Z breathe (Deseret Pharmaceutical Co. Inc.). Mask of three-ply construction, outer layers cellulose, inner glass fibre; simple folded design.
5. Filtron (3M Company, Medical Products Division). Mask of three-ply construction, outer layers cellulose, inner of polypropylene fibre; single box-pleat design.

Except for the Cestra mask they are all of the single-use, disposable variety, and are used directly from the boxes in which they are purchased. Except for the Aseptex they are held in place by pairs of fabric ties. All the disposable masks also have metal contour strips, which are pressed well down across the nose and cheeks in use.

Four trial runs were performed with each mask type, and all the masks were worn by the same subject throughout the investigation.

Counting

The colony counts recorded for each plate in each trial were obtained by using the 'positive hole count' method described in the instructions supplied with t Andersen sampler and a statistical correction appli according to the tables given by Peto and Pow (1970).

Results

The test procedure described yielded four sets colony counts for each trial. The Andersen sampl separates contaminant particles into six different si ranges which comprised each set as follows: plate >9·2 μm; plate 2, 5·5–9·2 μm; plate 3, 3·3–5·5 μ plate 4, 2·0–3·3 μm; plate 5, 1–2 μm; plate 6, <1 μ

In *Table I* the counts recorded are the totals for size ranges obtained in a total of 4 trials in each cas The 'background' count represents the number organisms entering the chamber while the head-p was open plus any organisms which passed throu the filter in the roof of the chamber. The 'maske count gives the total colonies obtained during t sampling periods when the masks were worn, wh the 'post-masked' count represents the residual a borne population still present in the chamber betwe 6 and 11 minutes after the end of the speech sequen giving rise to the organisms. The 'unmasked' cou represents the output of organisms resulting from t speech sequence and able to be collected within 5-minute sampling period similar to that used for t 'masked' count.

Table I shows that if the leakage of organis through or around the mask is calculated from t 'masked' and 'unmasked' data, there is no differen in efficiency between the Cestra, Surgine and Filtr masks, while the Aseptex and Filtermask desig appear to be somewhat less efficient. The same gene conclusion may be drawn if the calculations are bas on the total leakage, i.e. the 'masked' and 'po masked' counts as a percentage of the 'unmaske counts.

From *Table II* some comparison of efficiencies m be made in regard to performance in filtering lar particles (>3·3 μm) and smaller particles. It can seen that all the masks show a high degree of efficien of about 99 per cent in large particle filtration, b considerable differences in small particle filtrati efficiency exists. Again, the Aseptex and Filterma designs performed worst, however the data we calculated.

In *Table III* overall efficiencies are listed taking particles together, Aseptex and Filtermask aga performing the least well. Statistical tests of significan (*t*-test) performed on the data for total leakage valu showed no significant difference in efficiency betwe Cestra, Surgine and Filtron, while the difference w significant at the $P = 0{\cdot}05$ level between Filtron ar Filtermask, and at $P = 0{\cdot}1$ between Filtron ar Aseptex but just outside the significance level $P = 0{\cdot}05$.

Fig. 2 shows the distribution of particle sizes four from bacteria-containing droplets expelled from t subjects' mouth and nares during the course of t trials reported in this paper. It shows a marked different distribution from that obtained by t aerosolization of bacteria (or spores) using mechanical devices of various kinds, which has been drawn from the results of Garrow et al. (1971) using *Serratia marcescens*. It is not surprising that they differ significantly and that the distribution for the naturally expelled population should be skewed markedly to the left (i.e. towards large particle size) since the bacteria of the normal respiratory tract flora typically grow in clusters or aggregates, e.g. the Corynebacteria, streptococci, staphylococci, Neisseria, etc.

The histogram of our data was calculated from a total of 25 481 particles (corrected count) which were expelled during 2400 utterances of the word 'chew', giving an average of 10–11 colony-forming units per word.

Discussion

In deciding which test procedure should be used for the investigation of mask efficiency it was necessary to consider carefully what were the main objectives. We did not think a test of filtration efficiency of merely the mask material under *in vitro* conditions such as those devised by Rubbo and Abbott (1968) would be adequate since in use the mask is 'fixed' around an irregular surface (the face) and a certain amount of leakage around the edges would occur. Also, to pass a standard aerosol through clamped samples of fabric at a steady flow rate did not seem to be a good approximation of the situation *in vivo*.

Also, it was thought necessary that the mask should be subjected to the effects of abrasion and moisture which would obtain during use by a human subject, so on this basis all the manikin methods described in the literature were ruled out. Again, because of the problems of uneven distribution of expelled organisms, some of which passed through the mask and some of which were expelled 'backwards' around the edges, all methods involving freely exposed agar plates were also ruled out.

Therefore, in order, to obtain *in vivo* conditions a human subject was considered essential, and in order to collect all the organisms which leaked either through or around the mask an enclosed air volume which could be 'swept' over the receiving plates was also considered necessary. The special test chamber and Andersen sampler met these requirements.

We modified the procedure of Greene and Vesley (1962), who first used this type of chamber, in a number of ways. First, it was thought essential that the mask be worn for at least a reasonable period of time before commencing the tests as some fibres are hygroscopic and would perform differently when 'saturated' with moisture from, for example, exhaled air. A time of 30 minutes was chosen so that the masks would be already moistened and contaminated with organisms before the tests began.

Secondly, we found that saying the phrase 'sing and chew' six times (Greene and Vesley, 1962) produced very few organisms and so we changed the speech sequence to 120 repetitions of the word 'chew'. Also, since this sequence lasted for 4 minutes of the 5-minute sampling period, and the total 5-minute sample was only 5 ft^3 out of a chamber volume of nearly 8 ft^3, a subsequent 5-minute sampling period, the 'post-masked' sample, was added to the procedure.

Table I, which lists the counts obtained for the various masks, shows a number of interesting features. First, the background counts show that not more than an average of 6 contaminant particles per 5-minute sampling period were likely to enter the chamber adventitiously, i.e. through the filter or head-port. Strictly speaking, these adventitious contaminants

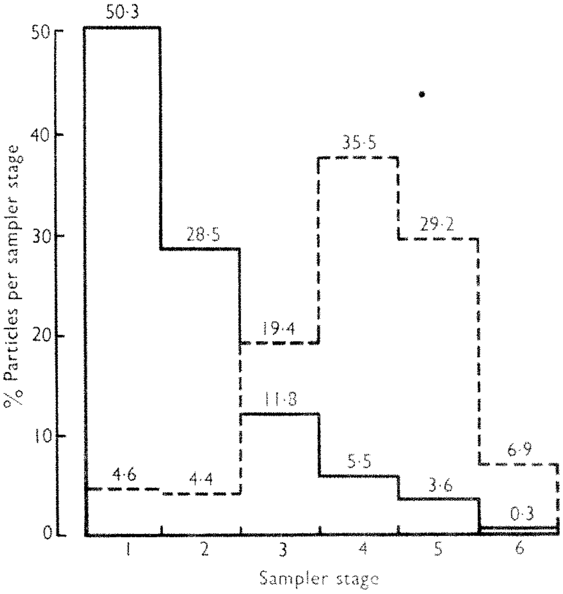

Fig. 2. The distribution of 'colony-forming units' by particle size. The histogram with entire margin was obtained by collecting together all the 'unmasked' counts and arranging the data as percentage of the total count for each stage of the Andersen sampler. The total count was 25 481. The histogram with broken margin gives the distribution of colony-forming units by particle size for aerosolized *Serratia marcescens* as found by Garrow et al. (1971).

Table II: LEAKAGES CALCULATED IN THE PARTICLE SIZE RANGES GIVEN FOR EACH MASK TYPE

	% Leak *b* of *d**		% Leak *b* + *c* of *d**	
Mask type	>3·3 µm	0–3·3 µm	>3·3 µm	0–3·3 µm
Aseptex	1·13	20	2·1	44·9
Cestra	0·62	10·96	1·37	32·89

Cestra	98·8	96·7
Surgine	98·8	96·5
Filtermask	95·8	90·8
Filtron	98·8	95·7

* *See Table I.*

would also be present during the other count periods to give an artificially raised count of leakage organisms. It would be possible to make a notional correction for this, but it was thought better to omit this and state that the efficiencies recorded were therefore slightly less than the true efficiencies of the masks concerned. On this basis it was interesting to note that the percentage leak obtained is nevertheless very low in absolute terms (column *e*, *Table I*), and if only large particles are considered, extremely low (*Table II*).

Secondly, in every case the 'post-masked' count was higher than the 'masked' count. This demonstrated two points, viz. that the initial sampling period was inadequate and that viable organisms could remain in aerosolized suspension for a considerable time. Greene and Vesley (1962) did not include a 'post-masked' count in their trials so it is not known how many of these organisms were missed by them. Separate tests showed that in our experiments the number of organisms still remaining after this second 'post-masked' sample was of the same order as the background count.

When the 'filtration' efficiency of the masks is examined relative to the different size ranges of large (> 3·3 μm diameter) and small (< 3·3 μm) particles it can be seen from *Table II* that large particle filtration is extremely efficient in all cases, while small particle filtration is comparatively inefficient, and that even the best masks were only 89–90 per cent efficient. Analysis of the data also reveals that the 'post-masked' counts in the case of Filtron and Surgine masks are about 2·5 and 2 times as great as the 'masked' counts, but only 1·5 times as great for the Cestra mask. This may be an indication that very fine filters generate small particles, which may be caused either by splitting of large particles as they impact upon the mesh or by filling the pores with liquid which then bubbles out and bursts under further pressure—the 'bubble tube' effect. It may well be that the Cestra mask was superior in performance because it was absorbant and did not readily permit the build-up of liquid films which would contribute to the 'bubble-tube' effect.

Table II also shows that the Aseptex and Filtermask designs had about half the small particle efficiency as the other 3 masks. We think that it is relevant in this regard that both of these masks were much narrower than the others, covering far less an area of the cheeks. In addition, they were both unpleated and rather stiff. These two factors would contribute to an increased leakage of organisms around the edges of the mask in that small particles would be more readily deflected backwards and more easily escape. Put conversely, it would appear that pleating contributed significantly to the efficiency of the mask in the case of the Filtron and Surgine, and the Cestra mask, while not pleated, was soft and extended well back over the cheeks and under the chin, covering a larger area than any of the other masks.

It should also be remembered that particles less than 3 μm in diameter will not easily fall on their own account, for example, into a wound during surgery. On the other hand, particles larger than 5 μm are very unlikely to enter the lungs, so that small particle inhalation would be the main hazard in situations of poor ventilation where open wounds were not involved.

A broad summary of the overall data is given in *Table III* and we may make the following general conclusions from the investigation:

1. The overall efficiency of all the masks is high, approaching 99 per cent for the best designs, viz. Cestra, Filtron and Surgine.
2. Large particle filtration efficiency was similarly high in all cases.
3. Small particle filtration efficiency was considerably lower, being worst in the Aseptex and Filtermask designs.
4. Inefficiency was probably affected as much by stiffness, lack of pleating and size as by deficiencies in 'filtration'.
5. Cotton fabrics may be as effective as synthetic fabrics when incorporated in a good mask design.

Identification of talc on surgeons' gloves and in tissue from starch granulomas

W. J. HENDERSON, C. MELVILLE-JONES, W. T. BARR AND K. GRIFFITHS*

SUMMARY

Particles of talc have been identified on the route surface of surgeons' rubber gloves and in sections of tissue classified as 'starch' or 'foreign body' granulomas. This analytical study indicates that under certain circumstances these granulomas could have been caused by talc contamination.

THE recognition that the use of talc as a surgical glove powder was responsible for the postoperative development of peritoneal adhesions and tissue granulomas at the site of operation (Lichtman et al., 1946; Eismann et al., 1947) stimulated the search for an inert absorbable substitute, and resulted in its eventual replacement by a starch powder (Lee and Lehman, 1947; Postlethwaite et al., 1949) which initially appeared to produce no ill-effects within the peritoneal cavity. There have, however, been numerous reports over the past two decades suggesting that the use of starch powder could also result in a granulomatous reaction similar to that produced by talc (Snierson and Woo, 1955; McAdams, 1956; Nash, 1971; Neely and Davies, 1971; Cohen and Safaie-Shirazi, 1973). Starch granuloma peritonitis secondary to the glove powder reaction has now become recognized as a clinical entity (Sobel et al., 1971), and Taft et al. (1970) suggested that the severity of the condition may be related to the type of starch used. The starch powder has also been shown to produce granulomas and adhesions in experimental animals (Lee et al., 1952; Perper et al., 1971; Ignatius and Hartmann, 1972).

However, the results reported here indicate that starch particles may not always be responsible for the development of the granuloma peritonitis and that contaminants of the dusting powder used on the surgeons' gloves must be taken into consideration.

Materials and methods

A modified extraction replication technique (Henderson, 1969; Henderson and Griffiths, 1972) was used to prepare a particulate preparation from histological sections of tissue reported to be 'starch', 'foreign body' or 'suspected talc' granulomas. After removal of the wax with xylene and dehydration with alcohol, the tissue section was ashed on a microscope slide in an oven by slowly increasing the temperature to 500 °C and allowing oxygen to flow over the section. After incineration, the particles were removed using a film of 7 per cent polyvinyl alcohol (PVA). A carbon film was deposited on to the PVA film *in vacuo*. The PVA was then dissolved in a hot water-bath, leaving the particulate material trapped in the carbon film. Areas of interest were then localized on reference electron microscope grids and a second carbon coat deposited to stabilize the particles under the condensed electron beam required for micro-analysis. Particles were analysed in the electron microscope micro-analyser (EMMA-4; AEI) as previously described (Henderson et al., 1975).

A similar extraction technique was used to obtain a particulate preparation from the surface of a series of surgeons' gloves manufactured by different companies. PVA was allowed to flow over specific areas of the gloves and then allowed to harden. The resulting film containing the particulate matter was removed and examined as described above.

The upper figure denotes the individual reference grid square examined, and the lower figure the number of talc particles/grid square.

Results

Light microscopy of sections from 6 starch granulomas studied showed the classic rounded particles with Maltese cross birefringence. The sections were also shown to contain significant quantities of talc particles. Talc, a magnesium silicate, was identified in the electron microscope micro-analyser by the characteristic Si : Mg ratio of approximately 3 : 1 (Henderson et al., 1973). *Table I* shows the quantitative amount of talc particles located on numbered reference electron microscope grid squares in the series of sections studied. Localization of high concentrations in a particular area of a grid could often be related to the presence of giant cells recognized by routine optical microscopy of adjacent histological sections. A typical area of particles within a grid square is shown in

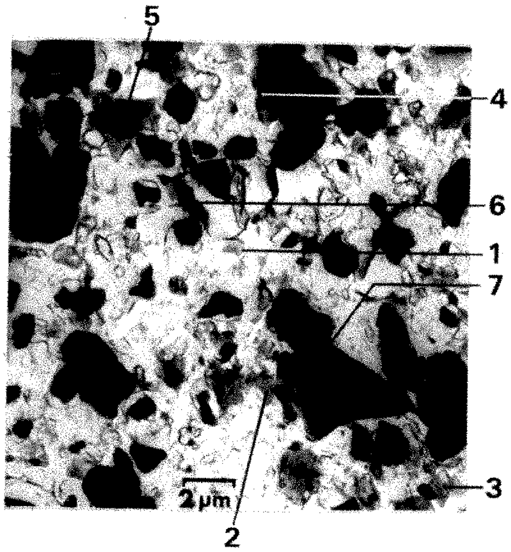

Fig. 2. Particulate material extracted from the external surface of a surgeon's glove. The individual analysis of the particles is shown in *Table V*.

Fig. 1. Analytical data for this series of particles are given in *Table II*. Tissue sections classified after histological examination as 'foreign body' granulomas rather than specifically implicating talc or starch were also studied. The number of particles of talc identified in these sections are shown in *Table III*. An average of two particles/grid square gives approximately 1600 particles/mm² tissue section. Three tissue sections classified as suspected talc granulomas (*Table IV*) were shown to contain large numbers of talc particles/grid square.

Surgeons' gloves (20 pairs) from companies in the United Kingdom were studied using the techniques described. These gloves were manufactured between 1973 and late 1974. At the same time 4 sample pairs of gloves from a company in Austria and another in the United States were obtained for simple comparative studies. *Fig.* 2 shows a typical group of particles extracted from the surface of a glove from a British manufacturer. The analysis of these particles is given in *Table V*. This was a typical result showing contamination of 8000 talc particles/mm² of glove

face. However, results varied with different ches of gloves. It was interesting that in the nples of gloves manufactured in other countries, no tamination was found on the Austrian gloves, ereas the samples from the American manufacturer e found to be heavily contaminated and a second A extraction was often necessary to allow singleticle analysis. It must be remembered that only a / limited number of gloves have been studied.

)ther elements detected in large amounts on the /e surface were zinc and sulphur. Whole fossilized coliths were often observed on the surface, and ıld appear to be responsible for the calciumtaining granules that were generally detected on ish gloves.

cussion

se results clearly indicate that the surgeons' gloves lied, manufactured in Britain and the United es, were contaminated by particles of talc. These ticles present on the outer surface of the gloves e extremely small, some 20 nm in diameter, and it ıld seem that in the manufacturing process the r systems used were inadequate to prevent access hese fine talc crystals. The normal procedures used checking such contamination may again be lequate to identify these particles and obviously not possess the resolving or analytical capacity of electron microscope micro-analyser. The gloves nufactured in the United States had even more talc ticles per unit surface area, whereas the Austrian /es studied appeared to be uncontaminated. The nt of such contamination cannot really be ssed from a preliminary study of this nature, but results of these investigations do suggest that it uld not be assumed that foreign body granulomas /hich starch can be identified are necessarily due to ch. Submicroscopic particles of talc which have n identified may also be concerned.

urthermore, analysis of the particulate content of a es of histological sections of tissue classified as ch or foreign body granulomas also showed that e tissues contained talc particles. This extraction nique has been used for the study of asbestos fibres nesotheliomas (Henderson et al., 1969), talc in rian tissue (Henderson et al., 1971; Griffiths et al., 3) and the particulate matter in tissue from nach tumours removed from Japanese men nderson et al., 1975). The use of EMMA-4 vides the sophisticated analytical technique by ch individual particles can be identified. Whether granulomatous lesions, the cause of which has n attributed to the presence of starch, resulted ead from the presence of contaminating talc on the geons' gloves cannot at present be decided. There several laboratory and clinical studies which icate that starch particles *per se* can produce nulomas and adhesions within the peritoneal ity. The findings reported here merely draw ntion to the fact that talc contamination of the ves must be seriously considered in relation to this drome.

It is interesting that earlier studies (Henderson et al., 1971; Griffiths et al., 1973) revealed the presence of talc particles deeply embedded in tissues of the female genital tract, and in particular in the ovary and in ovarian tumours. Although contamination of the surgeons' gloves initially made this work suspect, further recent analyses undertaken with even greater thoroughness and care confirmed the presence of talc particles embedded deep within ovarian tissue. It has been suggested that the source of this talc could well be various types of contraceptives and that the route of entry is the fallopian tube. In relation to this, a case has been reported of a young woman with acute peritonitis whose peritoneum was covered in granulomatous lesions which were found to contain corn starch (Saxen et al., 1963). The source of the starch was found to be the lubricant of her husband's contraceptives.

It is important to know that the principal British producer of surgeons' gloves, on being advised of these findings, located the source of the talc contamination. It was in a process unrelated to and physically separated from the process for the manufacture of the gloves. The use of talc has now been eliminated, but the company hopes to introduce a system whereby possible glove contamination can be routinely monitored.

NEW
Praxilene
vasoactivator
INJECTABLE
RELIEVES REST PAIN

NEW

for peripheral vascular disorders

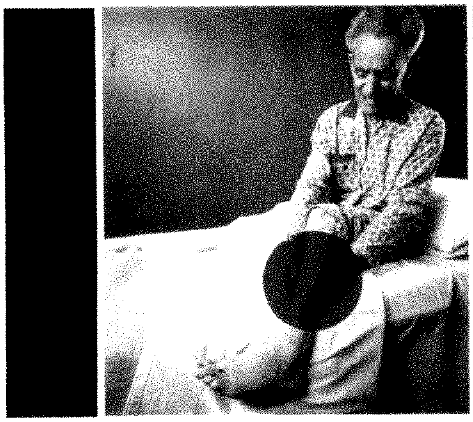
Praxilene

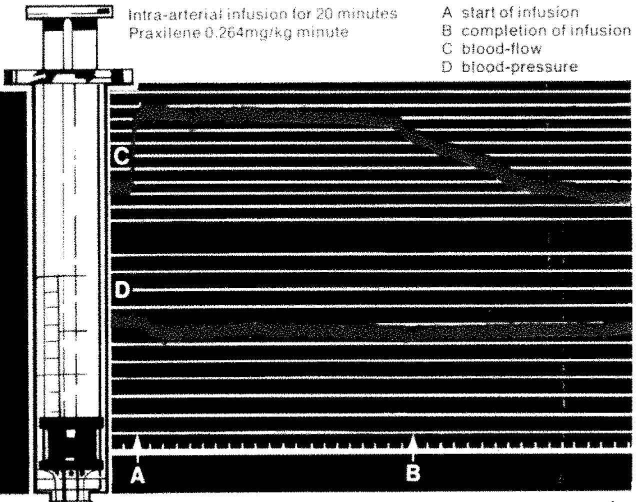
vasoactivator

INJECTABLE

RELIEVES REST PAIN

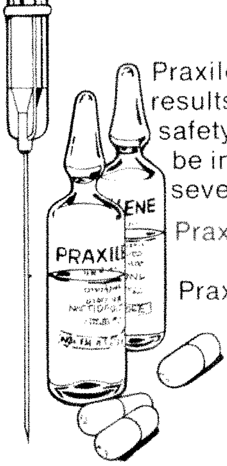
by flushing out pain producing metabolites
by improving blood-flow – without affecting blood-pressure
by a unique metabolic activity





Fast relief
Praxilene administered parenterally (Intra-arterial; Intravenous; Intramuscular) can give relief of pain within as short a time as one week, in many cases.

Prolonged relief
Relief of pain is prolonged: at the same time the collateral circulation is given the opportunity to develop, resulting in an improved blood supply to the affected limb.



Praxilene has produced excellent results because it has a very wide safety margin and the dosage can be individually tailored to the severity of the disorder.

Praxilene: Unique Vasoactivator

Praxilene: Naftidrofuryl: available as 40mg ampoules and 100mg capsules.

Full prescribing information and dosage schedule on request

The effect of metal clips on the tensile properties of healing skin wounds

I. D. HARRISON, D. F. WILLIAMS AND A. CUSCHIERI*

SUMMARY

The effects of nylon sutures and metal skin clips on the tensile properties of healing skin wounds have been studied in the pig. Wounds closed with clips have significantly poorer mechanical properties at 5, 7 and 14 days after wounding than similar wounds in the same animal closed with interrupted nylon sutures. This difference increased progressively with the period of retention of the clips. It is also shown that in equivalent groups of 14-day wounds, those in which clips were retained after the seventh day had a lower tensile strength, poorer ability to absorb energy and a lower elastic modulus than similar wounds where clips had been removed early. No such adverse effect was noted with nylon sutures.

METAL clips have been used for the closure of skin wounds for many years. The majority of surgeons have tended to restrict their use to wounds in the head and neck and have removed them at the earliest possible time. Early removal would appear to have been based on one of two possibilities, both untested: either that clips, being non-penetrating, allow healing to progress more rapidly than conventional sutures, or that clips, being potentially damaging, should be restricted to rapidly healing areas where early removal is possible. The increasing usage of clips and the appearance in the literature of reports of their use for general abdominal incisions (Annis, 1973) suggested that a critical assessment of their effects upon healing skin wounds should be made. We believe that the mechanical properties are the most important features to be considered in a healing wound.

The mechanical properties of wounds have been extensively investigated over many years. Only relatively recently, as a result of the work of Beckwith et al. (1963) and Glaser et al. (1965) in the United States and Gibson et al. (1965) in the United Kingdom, have the precise physical and engineering principles involved in testing the tensile properties of biological tissues been clarified.

There are three stages in the experimental procedure that require considerable care if meaningful results are to be obtained. First, since the mechanical properties of skin change very rapidly with time after removal from the body each specimen should be tested at the same time after removal. It is clearly impossible to cut, measure and test a large number of specimens simultaneously. However, since these changes are temperature dependent, rapid freezing of the specimens in liquid nitrogen at −196 °C, which halts this deterioration (Marangoni et al., 1966), allows individual specimens to be thawed separately when required for testing. Thus, a standard warm deterioration time may be used for all specimens.

Secondly, it is important to define the parameters which have to be measured and to choose the optimum conditions for their measurement. The mechanical characteristics of wounds (or normal skin) may be described in terms of four parameters:

1. *Maximum tensile strength*: This is the load per unit cross-sectional area of scar required to rupture the specimen (units: g/mm^2).
2. *Maximum tensile strain*: The degree by which the specimen elongates prior to rupture as a proportion of its initial length (units: mm/mm).
3. *Energy absorption*: The total amount of work which must be done on the specimen by the applied force, per unit volume, to cause rupture (units: $g\ mm\ mm^{-3}$).
4. *Modulus of elasticity*: This indicates the ratio of stress to strain when the specimen undergoes elastic deformation. The higher the modulus the 'stiffer' or less elastic is the specimen (units: g/mm^2).

All these parameters should be measured to characterize each specimen fully. As shown by their definitions, they are expressed in terms of the dimensions of the specimen tested, being either area, volume or length dependent. Much of the pioneering work (Sandblom, 1944; Douglas, 1952) measured only the breaking strength of wounds, the cross-sectional area of the scar not being measured. It is now realized that unless the dimensions are known, it is impossible to be sure that differences noted in breaking strength are real rather than apparent, since a greater thickness of some specimens can produce a greater breaking strength without any change in the true tensile properties. The measurement of the dimensions of the specimen is not straightforward since the application of any mechanical measuring device (e.g. micrometer) will distort the specimen, giving fallacious results. Indirect techniques such as photography are therefore necessary.

Finally, skin is a mechanically complex material exhibiting visco-elastic properties that vary with the strain rate. Forrester (1973) has discussed the methods available for controlling strain rate. Because of the complex nature of the material under test and the fact that the wound itself is heterogeneous it is vital that sufficient observations are made of each wound for a thorough statistical analysis to be carried out.

Materials and methods

Ten female Large White/Landrace cross-bred piglets, weighing 18–25 kg, were used in the trial. The pig was chosen for its relatively large size, lack of attachment of the skin to the panniculus carnosus and the close morphological similarity between its skin and that of man (Hartwell, 1955).

Two standardized linear incisions were created equidistant from the midline on the ventral surface of each animal. The incisions passed into the subdermal fat but did not divide the panniculus carnosus. In 8 pigs the wounds were 180 mm in length, and in each of these animals one wound was closed with 18-mm stainless steel Clay-Adams skin clips (Avlox, ICI) and the other with interrupted monofilament nylon mattress sutures (2/0 Ethicon), both being at 1·5-cm intervals. The nylon sutures entered the skin 1 cm from the wound margin and passed into the subdermal fat. The clips were applied from their specially designed applicator, thus avoiding variations in pressure of the clips on the skin. Wounding was carried out under general anaesthesia using strict aseptic technique, and during the healing period wounds were dressed with Elastoplast Airstrip dressings. A normal diet was taken throughout the trial.

For study each wound was divided into three equal areas, each containing four clips or four sutures (*Fig.* 1). One area of each wound was excised for mechanical testing after 1 week and another after 2 weeks' healing. The final area was also tested after 2 weeks' healing but differed in having had the clips or sutures removed on the seventh day, healing continuing in their absence for the final week. Any differences in the two groups of 2-week wounds should indicate whether the presence of clips or sutures aids or hinders the gain of tensile properties of wounds. The relative positions of the various wound areas were randomized.

The defect created by excision of an area of the wound was left unclosed but covered with a sterile non-stick dressing (Melalin) and isolated from the remainder of the healing wound by a waterproof dressing. It was felt that to attempt to close the defect would so distort adjacent tissues that the tension across the remainder of the healing wound would be markedly altered with consequent changes in healing rate. The unclosed defect, in fact, remained clean and granulated well (*Fig.* 2), and analysis of results from the rest of the wound showed no difference between the properties of specimens cut from areas adjacent to the unclosed defect, and specimens taken from some distance away.

The remaining pigs were utilized to study 5-day incisions. In these animals the linear wounds were 240 mm in length and each contained 16 sutures or clips. For excision purposes these wounds were divided into four equal parts, each containing 4 clips or sutures. Therefore an equal number of wound areas were available for study at 5 days as at the other time periods.

Following excision of each wound area, eight 2-mm wide specimens were cut with a specially fabricated cutter. These specimens had an approximately square cross-sectional area of scar, which is necessary for accurate testing (Glaser et al., 1965). Each specimen was then photographed in both plan and lateral view on a calibrated background using 35-mm colour transparency film. By projection of these views the width and thickness of scar could be very accurately measured and the cross-sectional area calculated—an essential preliminary to the determination of the tensile properties of any specimen.

Specimens, individually wrapped in aluminium foil and suitably labelled for identification, were stored in liquid nitrogen to halt the rapid change in the mechanical properties prior to tensile testing (Marangoni et al., 1966). All specimens in this trial had the same 'warm deterioration' times (18 minutes).

When required for testing each foil-wrapped specimen was thawed in water to room temperature, unwrapped, mounted on the Instron tensile testing apparatus (*Fig.* 3) and tested to failure. An automatic load/extension curve was plotted for each specimen, a total of over 500 being tested in this way. A constant gauge length of 25 mm was used. Because of the fragility of these specimens, especially the 5-day wounds, it was felt that the use of any strain gauge extensometer to measure and control the strain rate would affect the deformational behaviour during the test. It was therefore decided to use a constant extension rate (30 mm/min), accepting that a slight reduction of strain rate would occur during the test because of the constantly increasing length. In this way, all the specimens were subjected to a strain rate that was always within the range shown by Marangoni et al. (1966) to give reproducible results.

If the axes of the load/extension curve obtained from the Instron machine are corrected to those of stress (i.e. load/area) and strain (i.e. extension/original length), then the maximal tensile strength and strain may be read directly. The energy absorbed is represented by the area beneath the curve, and the modulus of elasticity by the slope of the essentially linear part of the curve (*Fig.* 4). The results obtained were statistically analysed by the paired *t*-test and analysis of variance methods.

Results

Macroscopic appearance

No infection was noted in any wound during the trial. Differences in gross appearance were obvious between nylon-closed and clip-closed wounds. It was seen that a progressive ulceration occurred at the site of contact of clip teeth with skin. This was slight at 5 days, obvious at 7 days (*Fig.* 5) and very gross by 14 days.

Mechanical properties

Tensile strength: Considering first only the wounds in which clips or sutures were retained throughout the healing period, it was seen that at all stages (i.e. 5, 7 and 14 days) wounds closed with nylon sutures had a significantly higher tensile strength than similar wounds within the same animal closed with clips (*Table I*).

Comparison of the strength of 14-day wounds in which clips had been removed after only 7 days showed them to be significantly stronger than similar wounds in which clips had been retained for the entire period. Retention of nylon sutures during the second week of healing produced an insignificant reduction in strength over similar wounds in which sutures were removed early (*Table II*).

Energy absorption: Less energy was required to disrupt clipped wounds than similar nylon-sutured wounds at all stages of healing tested. This difference reached significance level at 7 and 14 days (*Table III*). Comparing 14-day wounds it was seen that considerably more work was required to disrupt wounds from which clips had been removed early than those where clips had been retained for the entire 2 weeks.

5	23 ± 1·7	23·5 ± 2·6	$>$0·9 (n.s.)
7	28 ± 3·3	27 ± 1·6	$>$0·4 (n.s.)
14	28 ± 4·2	29 ± 5·4	$>$0·7 (n.s.)

Mean values and standard deviation (%).

Table VIII: TENSILE STRAIN OF WOUNDS AT 14 DAYS

	Sutures	Clips	*P* (paired *t*-test)
Early removal	28 ± 2·9	27 ± 2·9	$>$0·3 (n.s.)
Without removal	28 ± 4·2	29 ± 5·4	$>$0·7 (n.s.)
P (paired *t*-test)	n.s.	$>$0·2 (n.s.)	

Mean values and standard deviations (%).

In the case of nylon-closed wounds the energy absorption for the two groups was virtually identical (*Table IV*).

Modulus of elasticity: The modulus of elasticity was higher for nylon-closed wounds at all stages, this reaching significance level at 7 and 14 days (*Table V*).

Comparing 14-day wounds only, it is seen that the retention of clips throughout the healing period results in a markedly lower modulus than found in wounds where the clips were removed at 7 days. No significant difference was noted between the comparable groups of nylon-closed wounds (*Table VI*).

Tensile strain: No significant difference was noted in the tensile strain between nylon- and clip-closed wounds at any stage of healing. The retention of clips and sutures after the seventh day appeared to make no significant difference to the tensile strains of 14-day wounds (*Tables VII, VIII*).

Discussion

Careful control of the many variables in tensile testing has permitted a statistically valid assessment of the effects of skin clips on wound healing.

The relative importance of the four physical parameters measured is debatable. If a wound could be perfectly elastic, i.e. extend progressively under the influence of an applied force without any increase in tension within the wound, then the tensile strength of the scar would be unimportant. However, since this situation does not obtain and extension leads to progressively increasing tension within the wound, the maximum tensile strength is of vital importance. In the clinical situation all wounds are subjected to various forces tending to rupture them. This results in both extension and increase in tension within the wound, the ratio of these two components being indicated by the modulus of elasticity of that particular wound. Energy is absorbed by the wound as it deforms until saturation occurs, at which time the developed stress exceeds the maximum tensile strength of the scar and rupture occurs. It will be readily seen from this complex interrelationship why descriptions of wounds based upon only one of these parameters may be misleading.

It has been shown that wounds closed with clips are significantly weaker, have a lower modulus of elasticity and are able to absorb less energy than similar wounds in the same animal closed with monofilament nylon sutures. The differences in tensile strength may appear small, being 9 g/mm^2 at 5 days, 19 g/mm^2 at 7 days and 62 g/mm^2 at 14 days. However, if it is remembered that the average thickness of skin is approximately 2 mm, then for a 20-cm long incision (= 400 mm^2 area of scar) the breaking strength of a nylon-closed wound would be greater by 2·8 kg at 5 days, 7·6 kg at 7 days and 24·8 kg at 14 days than a similar wound closed with clips. There appears to be no difference in the tensile strains of the two groups.

It has also been shown that in equivalent groups of 14-day wounds, those in which clips were retained after the seventh day demonstrated markedly poorer tensile properties than similar wounds within the same animal where clips had been removed early. We feel that these results very definitely prove that the presence of skin clips has an adverse effect on wound healing. No comparable differences were noted in the case of nylon-closed wounds, and retention of nylon sutures appears to be without the adverse effect demonstrated by clips.

These results suggest that whilst skin clips have the benefit of speed of application, there are very real drawbacks to their use in areas of the body not normally associated with very rapid healing. In practical terms, this would restrict their use to the head and neck. Very early removal is possible in this region not because collagen synthesis occurs with great rapidity but because wounds are usually under little stress and if the subcutaneous tissues are adequately closed the skin edges will remain in apposition from the time that epidermal union has occurred (usually within 24–36 hours).

Conclusion

The possibility that clips may be removed earlier than conventional sutures because they permit wounds to gain strength more rapidly is shown to be untrue. Indeed, the prolonged retention of clips (in this trial after the seventh day) dramatically slows the gain of tensile strength, modulus of elasticity and energy absorption of skin wounds.

How tight should tension sutures be tied? A controlled clinical trial

I. L. ROSENBERG, T. G. BRENNAN AND G. R. GILES*

SUMMARY

In a prospective randomized trial there was no advantage in tying tension sutures flush with the wound; by tying them loosely (over three fingers of the assistant's hand) there was less wound pain and less cutting in of the tension suture into the ridge of the wound and along the suture tracks.

THERE is an opinion that tension sutures will protect against wound dehiscence (McCallum and Link, 1964), and many surgeons have advocated the routine use of these sutures in the closure of abdominal wounds. It is also true that tension sutures badly placed and tied too tightly will produce a very painful and infected wound and undo whatever advantage is gained in the protection of the wound. The present study has investigated the protection of paramedian wounds by tension sutures tied either loosely or in the usual manner, taking account of wound complications and wound pain.

Patients and methods

One hundred and twenty-eight patients undergoing laparotomy through a new paramedian incision were consecutively entered into a prospective trial; incisions through old scars were excluded from the trial. In all cases the incision was a laterally placed paramedian incision which was closed in layers. The peritoneum and anterior rectus sheath were each closed with continuous No. 1 chromic catgut and the skin with interrupted silk sutures. The tension sutures used were of No. 1 braided polyester coated with polytetrafluoro-ethylene on a 90-mm curved needle with 30-mm retention tubing (Ethicon Ltd). The tension sutures were placed deep to the rectus muscle, superficial to the posterior sheath, passing through all other layers and at intervals of 3–5 cm. The skin entry and exit holes of these sutures were positioned about 2·5 cm from the incision. After randomization, the tension sutures were tied with the loop flush on the skin but not tightly, or loosely with the loop tied over three fingers of the assistant's hand.

Initial wound assessment was conducted on the tenth postoperative day, looking for signs of infection, haematoma, presence of a healing ridge and cutting in of the tension sutures on the ridge or in the needle tracks. An assessment of wound pain was made by the nursing and resident staff and divided empirically into three groups: average, less than average and more than average. Careful note was also taken of the presence of postoperative sputum retention and chest infection. In almost all the patients the skin sutures were removed on the tenth day and the tension sutures on the fourteenth day. In a few cases removal of the tension sutures was delayed where the patient was cachectic or on high dose steroid therapy.

Final assessment was made at least 4 months postoperatively when the wound was examined for the presence or absence of an incisional hernia.

Table I: COMPARISON OF THE TWO GROUPS STUDIED

	Flush tied	Loosely tied
Total	55	58
Male	30	31
Female	25	27
Elective surgery	42	40
Emergency surgery	13	18
Clean laparotomy	13	11

Table II: SUMMARY OF THE FINDINGS

	Flush tied		Loosely tied		
	No.	%	No.	%	*P*
Burst abdomen	0	0	0	0	
Incisional hernia	1	2	2	3	
Wound pain					
Less than average	17	31	28	48	
Average	30	55	25	43	
More than average	8	15	5	9	
Wound infection	10	18	4	7	>0·05
Haematoma or sero-sanguineous discharge	0	0	5	9	
Normal healing	45	82	49	84	
Infected tension suture	3	5	3	5	
Cutting in along track	33	60	15	26	<0·001
Cutting in on ridge	26	47	10	17	<0·001
Chest infection	12	22	20	34	

Results

Of the 128 patients, 3 died of disseminated malignancy in the early postoperative period and were excluded from the analysis. Thus, the abdominal wounds of 125 patients were assessed on the tenth day; 60 patients had flush tied tension sutures and 65 patients had loosely tied tension sutures.

The two groups appeared well matched for numbers, sex, type of surgery and body build (*Table I*). *Table II* summarizes the findings of the study. It can be seen that there was no significant difference between the groups with regard to the incidence of wound infection, haematoma, serosanguineous discharge, infected tension suture tracks and chest infection. However, as might be expected, loosely tied tension sutures did not usually cut into the ridge of the wound ($P < 0{\cdot}001$) or through the suture holes ($P < 0{\cdot}001$). Wound pain was apparently less in patients with loosely tied sutures but this was not a statistically significant observation.

---

* University Department of Surgery, St James's Hospital, Leeds.

There was no instance of burst abdomen. Fifteen of the patients have been lost to the 4-month post-operative review, but of the 110 patients examined 4 months or more after operation, 3 had an incisional hernia (2 in the loosely tied group).

Discussion

It was not the intention of this study to judge the value of tension sutures in abdominal wound closure. However, the method of closure adopted for the present study appears satisfactory when compared with other reports (McCallum and Link, 1964; Goligher et al., 1975). Tension sutures presumably act by protecting the rectus sheath closure against increased intra-abdominal pressure due to coughing, bowel distension and paralytic ileus.

That abdominal wounds swell during the first week after an operation is a common observation, and flush tied tension sutures become tight and cut into the ridge of the wound and along the suture tracks. This was not the case with loosely tied sutures and the slack in the sutures was taken up by the oedematous wound. Presumably this tightening up of the loosely tied sutures enabled their protective action to continue. Since wound pain appeared lessened by tying the tension sutures loosely and there seemed to be no loss of the protective action of the sutures, when tension sutures are used they should be tied loosely over three fingers of the assistant's hand.

Does the choice of suture material affect the incidence of wound infection?

A comparison of Dexon (polyglycolic acid) sutures with other commonly used sutures in an accident and emergency department

G. L. MOUZAS AND A. YEADON*

SUMMARY

One hundred and four patients with superficial lacerations were sutured with either Dexon (polyglycolic acid), silk, polyethylene or nylon sutures. The incidence of postoperative tissue reaction and wound infection was compared.

There were few complications and these occurred with almost the same frequency in each suture group, although there were slightly more cases of infection in the patients who were sutured with silk.

Dexon was seen to possess certain advantages in that it caused as little tissue reaction as the other sutures but did not have to be removed subsequently. This could clearly be of benefit to the patients and hospital staff alike.

THE average casualty surgeon spends a large proportion of his time treating superficial lacerations. Clearly, the efficiency with which this treatment is carried out is of major importance to the patient and hospital service alike.

Although there are many factors related to wound healing that are outside the direct control of the casualty surgeon, there are undoubtedly many ways in which the surgeon and his team can improve the chances of a successful outcome when treating superficial lacerations of the skin. Nichol and Cole (1973) stated that damaged structures should be carefully inspected to ascertain the precise extent of the laceration, which should then be meticulously prepared with débridement of all devitalized tissue. Repair should be carried out skilfully, sutures should not be tied too tightly around the wound edges as this can markedly increase the incidence of infection and good postoperative care is essential to reduce scarring.

The choice of suture material may also be important since the physical and chemical properties of sutures can affect wound healing. Edlich et al. (1973) found that Dexon (a synthetic absorbable suture manufactured from polymerized glycolic acid—PGA) elicited less infection in contaminated subdermal tissues in the mouse than did gut sutures. These workers also stressed the fact that the chemical properties of the suture appeared to be the most important determinant of early postoperative infection, and amongst the absorbable sutures examined in this study PGA appeared to elicit the least inflammatory response in contaminated tissues. Lilly et al. (1973) studied PGA sutures *in vitro* and found that they transmitted bacteria less readily than silk sutures.

In view of these reports and the fact that many lacerations treated in an accident and emergency unit are grossly contaminated, we decided to set up a clinical trial to determine whether the incidence of complications such as tissue reaction and wound infection can be affected by the choice of suture material.

Materials and methods

Four different sutures were studied. These were Dexon, silk, polyethylene and nylon—all sutures which are in common use in accident departments.

Any patient with a skin laceration which did not involve deeper structures was eligible for inclusion in the trial. A careful note was made of the patient's name, age, sex and history. The wound was examined and a note made of its size and extent. The degree of contamination was assessed not only by inspection but also by determining the precise circumstances of the injury and its management before arrival at the hospital. It was recognized, however, that only a very crude assessment of contamination was possible by these means, and as a result wounds were labelled either 'contaminated' or 'uncontaminated'.

Next the lacerations were cleaned and any débridement carried out. As far as possible the choice of suture material was made randomly, although there was a tendency to use Dexon sutures for children since this would avoid suture removal later. Wounds were covered with dry dressings.

All the patients were asked to return for at least two follow-up visits, the first after 2 or 3 days and the second after 7–10 days. At follow-up the wounds were inspected and a note was made of the degree of tissue reaction and infection. If pus was present this was noted and a swab was sent for bacteriological examination. The degree of inflammation was ranked according to the following scale:

0, No reaction, normal healing.

1, Oedema present (this was only recorded if the oedema involved two or more adjacent sutures).

2, Oedema and erythema, probable infection. (Again, erythema was only recorded when it involved two or more sutures. The erythema confined to the needle puncture site was recorded as normal.)

---

* Accident and Emergency Centre, West Hill Hospital, Dartford, Kent, and Davis & Geck, Cyanamid of Great Britain Ltd, Gosport, Hants.

Present address of G. L. Mouzas: Chace Wing, Enfield District Hospital, Middlesex.

3, Oedema, erythema and pus. This was taken as an indication of definite infection and the patient was treated with an antibiotic.

The non-absorbable sutures were removed at the second visit, whereas the Dexon PGA sutures were merely trimmed if necessary. Any patient whose wound was still infected at this stage was asked to return for a further review a week later.

Photographs were taken of some of the typical or interesting cases to allow comparison at a later date.

Results

One hundred and four patients entered the trial. Of these, 71 (68 per cent) were male, with an average age of 32 years (range 2–67 years), and 33 (32 per cent) were female, with an average age of 22 years (range 1–70 years).

The patients in the Dexon group were younger than the mean because there was a tendency to use this material in children since removal was not required. The average age of this group was only 18 years. The average age of the silk group was 30 years, the polyethylene group 26 years and the nylon group 39 years.

Table I shows the number of patients, male and female, who were sutured with each type of material. Contaminated and uncontaminated wounds were fairly evenly represented in the four comparison groups. However, the distribution by sex was not so good since, overall, 68 per cent of the patients were male and 32 per cent were female, and in some subgroups, e.g. patients with contaminated wounds which were sutured with polyethylene, there were 13 males and only 1 female. The split in this group is clearly unrepresentative of the whole.

Table I: DISTRIBUTION OF PATIENTS ON ENTERING THE TRIAL

	Contaminated wounds				Uncontaminated wounds				
Suture used	M	F	Both	%	M	F	Both	%	Total
Dexon	11	4	15	58	6	5	11	42	26
Silk	12	2	14	54	6	6	12	46	26
Polyethylene	13	1	14	61	7	2	9	29	23
Nylon	10	7	17	65	6	6	12	35	29
All suture groups	46	14	60	58	25	19	44	42	104

M, Male; F, Female.

Only 3 patients failed to attend the first follow-up at 2–3 days, one from each of the Dexon, silk and nylon groups. A further 11 patients failed to keep their second follow-up appointment, so that the final number completing the trial was 90. The suture groups contained almost equal numbers of patients at this final assessment.

Table II compares the appearance of the wounds in each suture group after 2–3 days and 7–10 days. The sexes are shown together in the results, since a preliminary analysis of the data indicated no real differences in healing response that could be attributed to sex. Wounds which were classified as contaminated are shown separately from those that were not. In general, the wounds that were originally considered clean showed less tissue reaction and infection than those that were contaminated. For instance, at the first assessment 43 per cent (25 of 58) contaminated wounds looked normal as opposed to 63 per cent (27 of 43) of the clean wounds. By the second assessment at 7–10 days, the difference was less marked: 68 per cent (39 of 57) contaminated wounds looked normal as opposed to 79 per cent (26 of 33) clean wounds. However, these differences are not statistically significant.

Since whether or not the wound was initially thought to be contaminated seemed to have little bearing on the outcome of wound healing, the results shown in *Table II* have been summarized in *Tables III* and *IV*. These tables present the results of contaminated and clean wounds together for each suture group at both assessment stages.

* *See* text.

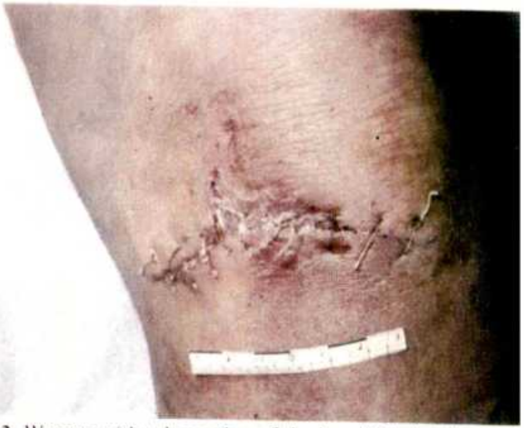

Fig. 3. Woman with a laceration of the leg which had been sutured with Dexon 10 days before. There is some oedema present at either end of the wound. This was graded as 1.

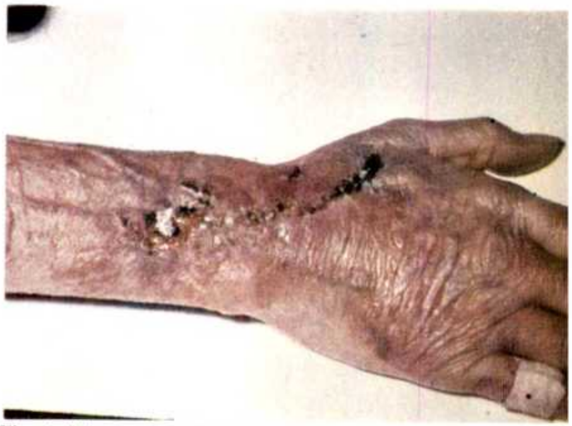

Fig. 4. Elderly man with a severe and contaminated laceration of the hand and forearm which had been sutured with silk. Oedema, erythema and pus are all present.

At 2–3 days there was very little difference between the number of wounds that appeared normal in each suture group, but whereas only 1 wound in each of the Dexon, polyethylene and nylon groups was frankly infected, 4 of the wounds sutured with silk were infected. These 7 patients were given antibiotics after a swab had been taken.

By 7–10 days 77·3 per cent (17 of 22) of the Dexon wounds, 68·2 per cent (15 of 22) of the polyethylene wounds and 73·9 per cent (17 of 23) of the nylon wounds were normal in appearance, whereas only 56·5 per cent (13 of 23) of the silk sutured wounds were considered normal. This difference, although interesting, is not statistically significant ($\chi^2 = 1{\cdot}7858$, d.f. = 3, $0{\cdot}70 > P > 0{\cdot}50$).

Four wounds were still infected at the second assessment—3 in the group sutured with silk and 1 in the polyethylene group. The antibiotic was changed in 2 of these and all were improving when they were seen a week later.

Figs. 1–4 give some indication of the type of reactions observed.

Conclusions

In this study an attempt was made to examine the degree to which the choice of suture material could affect the incidence of tissue reaction and wound infection in superficial lacerations.

It was interesting that the degree of initial wound contamination did not appear to affect the incidence of infection significantly. This may have been due to the fact that only relatively small numbers of patients were examined or that the criteria for judging a wound contaminated or not were insensitive.

When all the results are taken together (*Tables III* and *IV*) there appear to be no significant differences in the incidence of tissue reaction between the four sutures examined. There was a tendency, however, for more silk wounds to become infected. This was true at 2–3 days and 7–10 days. Synthetic non-absorbable sutures such as nylon are well known for their inertness. In this study Dexon, a new synthetic absorbable suture, performed as well as the non-absorbable materials, causing as little trouble as nylon and polyethylene, and fewer cases of tissue reaction and infection than silk.

On the basis of these findings it would seem that Dexon sutures have certain advantages over the other sutures tested, in that, whilst they perform just as well, they could save the medical and nursing staff time, the Hospital Service money and the patients the trouble of follow-up visits for suture removal.

Gangrene of the tongue following self-application of a rubber band

T. DUTTA AND K. VASUDEVAN*

SUMMARY

A case of dry gangrene of the tongue due to self-application of an elastic rubber band in a mentally retarded child is described. As far as is known, no such case of gangrene of the tongue has been described in the English literature.

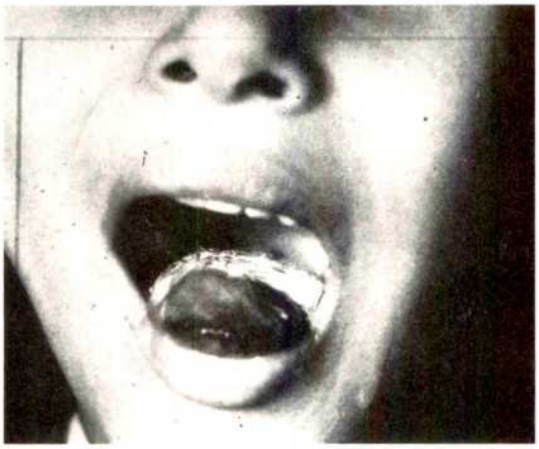

Fig. 1. Tongue on presentation showing gangrene of its anterior third.

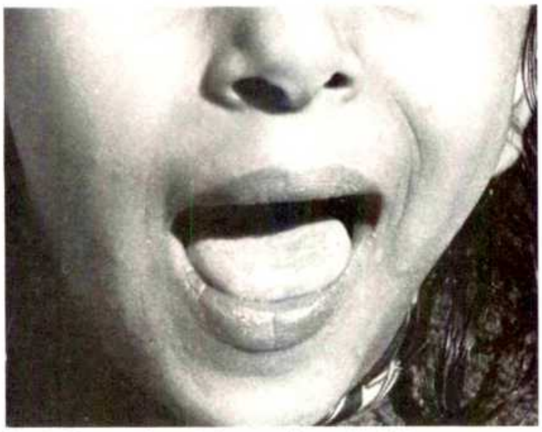

Fig. 2. Tongue 4 weeks later, with no disability.

GANGRENE of the tongue is extremely rare. The tongue is one of the most vascular organs in the body and any vascular insult is quickly overcome by the rich blood supply.

Case report

M. K., an 8-year-old female child, was examined in the children's surgical outpatients' department of Safdarjang Hospital, New Delhi, in October 1974, because of a 'black patch on the tongue' which had been present for 3 days. Two days earlier the parents had noticed that the child had difficulty in speaking and eating food, and the tongue was swollen and discoloured.

Examination revealed a frail mentally retarded child. Systemic examination was normal. Local examination revealed a distinct groove of 0·5 cm depth at the junction of the middle and anterior thirds of the tongue beyond which the tongue was black and shrivelled (*Fig.* 1). At the bottom of the groove there was a stretched rubber band which was the cause of the strangulation of the distal third of the tongue. The child confessed that she had applied the rubber band 3 days earlier. Her parents had not noticed it.

The distal one-third of the tongue which was gangrenous had no sensation and did not bleed on pricking. The proximal two-thirds of the tongue were normal. The child's speech was indistinct (dyslalia), and she was unable to stick out her tongue.

The rubber band was removed immediately and oral penicillin administered.

The gangrenous part of the tongue withered and fell off 3 days later without any bleeding. The child was seen in the surgical follow-up clinic 4 weeks later and was apparently having no difficulty in speech or deglutition. The tip of the tongue was smooth and rounded and had normal mobility (*Fig.* 2).

Discussion

The whole episode was of short duration and the gangrenous part of the tongue separated off rather quickly because of the rich vascularity of the tongue, and perhaps also because the necrosis may have been mainly confined to the mucosa and submucosal layers, as in ring strangulation of the penis. There were no later complications. A search of the literature has failed to reveal any similar report of gangrene of the tongue.

The pick of the bunch for skin disinfection

'Dispray' 1 Quick Prep. (formerly known as Hibispray 1) is an ideal preparation for skin and hand disinfection in the busy hospital environment.

At the touch of a button it gives fast, easy and economical skin disinfection prior to surgery, injection or venepuncture.

When colour delineation is required eg. pre-operatively, 'Dispray' 3 is available with a red dye.

The 'Dispray' range combines effectiveness with convenience and economy.

Instant Availability.
No solutions to prepare.

Easy to use.
No swabs or bottles required.

Quick and Effective.
Rapid bactericidal action.

Efficient Application.
No wasted solutions.

Contents cannot be contaminated.
No rejected solutions.

Long Lasting.
Contents of one can treat 100 sq. ft.

When pseudomonas threatens...

Pyopen

The skill of the surgical team,
hours in the theatre, the most advanced
techniques in the world . . . and infection
can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen – by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by

In situ intraduct carcinoma of the breast: a long term follow-up study

R. R. MILLIS AND G. S. J. THYNNE*

SUMMARY

Twenty-eight patients with in situ intraduct carcinoma of the breast are reviewed. Two patients had bilateral tumours. The numbers of patients treated by wide local excision, simple mastectomy and mastectomy with axillary dissection were approximately equal; none of these patients died of carcinoma. The conclusions regarding prognosis and treatment of in situ intraduct carcinoma of the breast are discussed.

THIS study of 28 cases of intraduct carcinoma diagnosed at the Royal Marsden Hospital between 1948 and 1968 has been undertaken to determine the natural history of this condition.

Intraduct carcinoma frequently contains microcalcification which is often detectable by radiological examination of the breast before a mass can be felt or seen on an X-ray. Radiological examination is now used in conjunction with other methods of examination for the earlier diagnosis of breast cancer, in particular in the screening clinics recently established. The early manifestations of breast carcinoma include *in situ* lobular carcinoma and *in situ* duct carcinoma. Much is known about the long term results in patients with *in situ* lobular carcinoma (McDivitt et al., 1967; Hutter and Foote, 1969; Haagensen, 1971; Anderson, 1974; Wheeler et al., 1974), but fewer groups of patients with *in situ* duct carcinoma have been studied (Gillis et al., 1960; Farrow, 1970; Ashikari et al., 1971).

Materials and methods

All histological reports of carcinoma of the breast made in the Royal Marsden Hospital Pathology Department between 1948 and 1968 have been studied, and relevant sections of cases in which the diagnosis may have been *in situ* duct carcinoma have been reviewed. Extremely strict histological criteria have been applied and only those in which a histological diagnosis of *in situ* intraduct carcinoma can now be made with certainty have been included. Haematoxylin and eosin sections have been examined, new sections being prepared, as well as a section stained for elastic and other special stains when indicated. The following cases were excluded: those in which the biopsy was small, such as a drill biopsy where it is not possible to be certain that the material is representative; those in which only slides referred from another hospital for a second opinion were available; those in which there was any suggestion of invasion, either in the original slides or in recuts from the blocks. Cases with Paget's disease associated with underlying *in situ* intraduct carcinoma have also been excluded, since there is still much debate concerning the source of the malignant intra-epidermal cells. One patient excluded gave a history of removal of the other breast for invasive carcinoma a few years previously. Three cases of intracystic carcinoma have been included in the study (McDivitt et al., 1968).

From a review of 85 cases, a total of 28 patients with *in situ* intraduct carcinoma have been considered acceptable for detailed study. Two patients had bilateral tumours (i.e. 30 tumours). Seventeen of the cases were diagnosed between 1948 and 1963 and 11 between 1964 and 1968.

Results

The details of the history, clinical findings, treatment and follow-up are shown in *Table I*.

Age distribution and menopausal status

The age and menopausal status of the patients at the time at which the diagnosis was made are shown in *Table II*, the patients being grouped by decades. The mean age was 55 years and the range 39–84 years.

Family history

The family history had not been recorded in 11 cases. A family history of carcinoma of the breast was present for 7 of the 17 patients for whom this information had been recorded. Two of these 7 patients had, in addition, a family history of carcinoma in sites other than the breast, and 2 other patients gave a family history of carcinoma at another site.

Marital status, parity and breast feeding

Eighteen patients were married and 10 single. The 10 single patients were nulliparous. Of the 18 married women, 6 had had 1 child, 7 were multiparous and parity was unrecorded in the other 5 patients. Breast feeding was not recorded with sufficient frequency to permit adequate analysis. None of the patients had presented during pregnancy or lactation.

Clinical presentation

Twenty-four patients presented with a clinical mass, 2 of whom had bilateral masses. Six of these patients also gave a history of pain and 5 a history of nipple discharge, which was bloodstained in 2 cases. Discharge or bleeding from the nipple was the only abnormality found in 3 patients. One patient's only complaint was of pain in the breast.

Table III gives the size of the palpable mass at the time of presentation.

					2 mth	Right: lump and nipple discharge	5-cm mass		Right: intracystic			

NR, Not recorded.

In 11 patients axillary lymph nodes were palpable, and in 3 these were thought to be significant.

Duration of symptoms

The duration of symptoms before presentation was less than 3 months in over half the patients and over a year in only 3 cases. One patient gave a history of a mass for 5 years. For 1 patient the duration of the presenting symptom was not recorded.

Treatment

Table IV lists the initial treatment given to each patient. Over half the patients were treated by wide local excision or simple mastectomy.

In 3 of the 9 patients treated by wide local excision a diagnosis of *in situ* intraduct carcinoma was made by frozen section. In 1 case the frozen section was negative, and in 5 patients a frozen section was not requested.

Four surgeons were associated with the treatment of the patients in this series. Two did not perform a radical mastectomy for this disease. The other 2 surgeons practised various operations, tending to reserve wide local excision for patients who had had a previous contralateral mastectomy, for the elderly and for those with severe systemic disease, thus performing a radical mastectomy only on the younger patients of the series. One patient with severe cardiac asthma was treated by radiotherapy alone.

Table II: AGE AND MENOPAUSAL STATUS OF PATIENTS

Age (yr)	No. of cases	Menopausal status
31–40	3	All premenopausal
41–50	11	6 premenopausal 3 menopausal 2 post-hysterectomy
51–60	5	All postmenopausal
61–70	5	All postmenopausal
71–80	2	All postmenopausal
81 and over	2	All postmenopausal
Total	28	

Table III: CLINICAL SIZE OF MASS ON PRESENTATION

Size of mass (cm):	No. of cases:
>5	6
2–5	10
<2	5
No mass	3
Not recorded	6
Total	30

Table IV: TREATMENT

Treatment:	No. of cases:
Wide local excision	9
Simple mastectomy	10
Extended simple mastectomy	3
Radical mastectomy	7
Radiotherapy only	1
Total	30
Radiotherapy preoperatively	1
Radiotherapy postoperatively	2

Radiotherapy was given preoperatively to 1 patient treated by radical mastectomy. Postoperative radiotherapy was given to 1 case treated by a simple mastectomy and to 1 treated by wide local excision.

There were 2 patients with bilateral intraduct carcinomas of the breast. One was treated by wide local excision on one side but had radical mastectomy on the other side because of clinically significant ipsilateral lymph nodes. The other patient, who died in the immediate postoperative period, had bilateral simple mastectomies.

Follow-up

One patient who was a poor operative risk (84 years old with hypertension) developed cardiac arrhythmia and died in the immediate postoperative period. One patient returned abroad immediately after operation and has not been followed up since at the Royal Marsden Hospital.

The patient treated by radiotherapy alone died at 7 years with skeletal metastases.

Of the other 25 patients, 3 died before the 10-year follow-up, and 2 between 10 and 14 years after operation (*Table V*). All 5 patients died of other causes, without clinical signs of recurrence. Two patients were lost to follow-up after 15 years but were alive and well without recurrence when last seen.

The remaining 18 cases are still being followed up and are at present alive and well. Eleven have been followed up for over 10 years and 7 for over 5 years. Two in the latter group had recurrences.

Recurrence and metastases

In 2 patients there was local recurrence after initial treatment by wide local excision. In one this occurred 6 months postoperatively and was treated by radical mastectomy. In the other patient a recurrence at 7 years was also treated by wide local excision, but a second recurrence at 8 years was treated by simple mastectomy. Both patients are still alive with no further sign of disease.

The patient who succumbed with known skeletal deposits died 7 years after treatment by radiotherapy only.

Table V: FOLLOW-UP

Pathological features

A total of 30 tumours from 28 patients have been studied. In many of the earlier cases the macroscopic description was brief and sometimes not very clear. However, the most common features mentioned were prominent or cystic ducts, sometimes associated with a firm area. Creamy exudate was described in the cases of typical comedocarcinoma. In other cases an ill-defined firm area was the only abnormality noted. A cyst was described in the 3 cases of intracystic tumour. No abnormality was remarked upon in 5 cases, and the gross appearance was not described in 3.

Size

The size of the lesion had not always been recorded in the gross description and it was often not possible to determine whether the lesion had been multifocal. However, judging from the size of the lesion sectioned, 6 cases appear to have involved less than 1 cm of breast tissue, 9 cases probably extended from 1 to 2 cm and in 15 cases the lesion involved more than 2 cm of breast tissue. There appeared to be no correlation between the size of the pathological lesion and the clinical presence of a mass, or with the clinical size of mass where this was recorded.

Histology

A summary of the histological features of the tumours can be seen in *Tables VI* and *VII* (McDivitt et al., 1968).

Pattern: The pattern of the lesion within the ducts was in most cases varied and mixed, with a single or multiple layer of malignant cells lining the duct. Frequently, the whole lumen was occluded by malignant cells, usually with necrosis of the central area producing the typical comedo pattern, and this pattern was seen alone or predominated in 12 cases. In 5 cases a thin layer of lining cells, often with a low papillary pattern, was present; in 8 cases there was a predominant cribriform pattern, and in 2 cases a mixture of patterns. In all these cases multiple ducts were involved. Three patients had intracystic papillary carcinoma. In 2 of these the lesion was markedly papillary with fairly well-developed fibrovascular stalks; in the other the tumour was more solid with supporting stalks poorly developed or absent. In none of these cases was the cyst wall invaded.

In patients who presented with a nipple discharge or bleeding all types of histological pattern were seen. One of these patients had an intracystic papillary carcinoma.

Nuclear features: Nuclear pleomorphism was variable and most marked in the typical comedocarcinomas where giant cells were numerous. However, marked pleomorphism and occasional giant cells were also present in some of the lesions in which there was only a thin layer of malignant cells lining the ducts. The mitotic rate was also variable and was often highest in patients with a comedo pattern where there was also marked nuclear pleomorphism. The intracystic carcinomas showed varying degrees of nuclear pleomorphism, but in none was the mitotic rate high.

Other features: Necrosis was present to a variable degree in most of the lesions, and was especially prominent in comedocarcinomas. Calcification was present in 10 cases and was usually found in the area of central necrosis in the comedocarcinomas. It was not found in this series in any of the 3 intracystic carcinomas. In 1 case calcification was localized within dilated adjacent non-malignant ducts. Mucin secretion was evident in the haematoxylin and eosin sections in over half the tumours, but was not a prominent feature. In 1 intracystic carcinoma mucin secretion was prominent and surrounded the papillary fronds.

Lymphocytic infiltrate around the malignant ducts was variable and was only prominent in 4 comedocarcinomas. Condensation of the stroma was sometimes seen around malignant ducts, but even with the use of Weigert's elastic stain elastosis was not demonstrated.

Dysplasia, most commonly fibrocystic disease, was seen in the surrounding tissues in over half the cases.

Lymph nodes from all the cases treated by radical mastectomy, including the 3 patients with significant clinical nodes, were free of metastatic carcinoma.

Nuclear pleomorphism was prominent in the lesion from the patient who died with metastatic carcinoma and in the lesions from the 2 patients with local recurrence, but in none was the mitotic rate high. In the patient who had two local recurrences the histological pattern showed a thin layer of malignant cells lining the duct, sometimes producing a low papillary pattern with marked nuclear pleomorphism but few mitoses. Both recurrences showed the same pattern. In the other patient with a recurrence a comedo pattern was present on both occasions. Tissue from the patient who died showed a mixed pattern but was insufficient for further comment. Since it was an incisional biopsy it could well have represented intraduct carcinoma around the edge of an infiltrating carcinoma.

Simultaneous bilateral carcinomas were present in 2 patients. One patient had a cribriform pattern on one side and an intracystic papillary carcinoma on the other. This patient died in the immediate postoperative period. In the other patient the malignant ducts showed a comedo pattern on one side and a cribriform pattern on the other.

Discussion

The small number of cases in this review, found over a period of 20 years, indicates a low incidence of diagnosis of this disease without accompanying infiltration. The numbers compare well with the study by Gillis et al. (1960), from the Mayo clinic, who found 36 cases of pre-invasive intraduct carcinoma after a study of 603 cases diagnosed as comedocarcinoma from 1928 to 1955. Figures from the Memorial Hospital, New York (Farrow, 1970), indicated an overall incidence of *in situ* carcinoma of the breast of 12 per cent, of which 30 per cent were the *in situ* intraduct type, i.e. approximately 4 per cent of all the breast carcinomas diagnosed. Their figures also showed an increase in the diagnosis of non-infiltrating mammary carcinoma during the 19 years preceding 1970. Another more recent report from the same centre (Ashikari et al., 1971) described 143 patients with intraduct carcinoma during the 10-year period 1960–9.

Some authors have suggested that the low incidence of intraduct carcinoma may be an indication of the aggressive nature of this lesion, i.e. it rapidly becomes invasive and progressive (Gillis et al., 1960; Somers, 1969). However, the good survival in the long term follow-up in the present series, and the fact that the 2 recurrent cases both remained *in situ*, does not support this view, and suggests, on the contrary, that these tumours do not have an aggressive behaviour.

There have been no controlled studies to confirm that untreated cases of *in situ* intraduct carcinoma eventually progress to invasion. However, several studies carried out have demonstrated the multifocal nature of this disease. That 2 out of 6 cases treated by wide local excision recurred and that 2 patients had bilateral *in situ* carcinoma tend to support this, and lend emphasis to the need for a diligent search for a second carcinoma. With increasing use of radiological examination of the breast, more cases of *in situ* intraduct carcinoma are being detected by the presence of micro-calcification before a mass is palpable. Is this because more cases of ductal carcinoma are being detected earlier or because more cases of a separate disease which remains *in situ* for a long time are being detected by this new method of investigation?

In this series a lump in the breast was the major presenting symptom. Pain and nipple discharge were also common. Each occurred as the only symptom in 1 case. (This underlines the need to investigate patients who present with these symptoms alone.)

Over half the patients presented within 6 months of the onset of symptoms. The patient who had felt a mass 5 years before presentation had bilateral tumours, was 84 years old and died in the early postoperative period. The 2 patients who presented at 3 years and 18 months after the onset of symptoms are still alive after 16 years and 26 years respectively.

The higher incidence of carcinoma of the breast in nulliparous women and those with a strong family history is again shown in this study.

The histological classification of non-infiltrating intraduct carcinomas differs at different centres. Muir (1941) recognized incipient duct carcinoma as lesions in which there were heaped-up papillae, a cribriform network or multiple solid foci. Haagensen (1971) divided intraduct carcinoma into four types: comedo, solid, cribriform and low papillary, and considered that approximately 15 per cent of carcinomas of the breast were of this type. McDivitt et al. (1968) described three types of non-infiltrating duct tumours, namely non-infiltrating papillary carcinoma (cribriform), non-infiltrating solid or comedocarcinoma and intracystic carcinoma.

Somers (1969) suggested that the degree of nuclear differentiation in *in situ* intraduct carcinoma is higher than in infiltrating carcinoma, reflecting the enhanced invasive capacity of less differentiated mammary carcinoma cells. Similarly, Gillis et al. (1960) thought that the malignant process began as a proliferation of cells lining ducts producing an ingrowth, often papillary, of well-differentiated cells with few mitotic figures. This process progressed to a more solid intraduct tumour coalescing to produce a cribriform pattern, and eventually forming a solid mass of cells with a progressive increase in anaplasia and mitotic activity.

There have been reports (Muir, 1941; Ashikari et al., 1971) of metastases in axillary nodes in cases of *in situ* intraduct carcinoma where no actual infiltration of the stroma of the breast could be demonstrated. In whole organ studies, Gallagher and Martin (1969) found lymph node metastases in 2 cases where only intraduct lesions could be found in the breast. Studies using the electron microscope have indicated that invasion is present in most cases presumed to be non-infiltrating by light microscopic examination (Ozzello, 1971).

The need for extensive studies of multiple blocks and multiple levels to exclude evidence of small foci of stromal invasion is well recognized, and because of the extreme diffculty of determining the absence of such foci some authors hesitate to recommend anything less than radical mastectomy as curative (Gillis et al., 1960; Farrow, 1970; Ashikari et al., 1971). However, Silverberg and Chitale (1973), in a study to assess the significance of proportions of intraductal and infiltrating tumour growth, found after a study of their series and a review of the literature 'that women with pure intraduct carcinoma (which should be diagnosed only after multiple permanent sections) can safely be treated by less than radical mastectomy and should have virtually normal life expectancies after treatment'. The present series supports this contention.

Conclusion

The numbers in the present series are too small to draw any firm conclusions as to the best treatment, but do support the relatively favourable prognosis in this type of breast carcinoma.

There was no difference in survival between patients treated by wide local excision or simple mastectomy and those treated by radical surgery. In 2 cases local recurrence after wide local excision was treated by more radical surgery. Neither of these patients has died of the disease.

It would seem justifiable to treat young patients (under 35 years), where radical therapy is less acceptable, and older patients (over 70 years) by wide local excision and careful follow-up at regular intervals.

Patients between 35 and 70 years are probably best treated by mastectomy and low axillary node dissection.

Even if the electron microscopic studies are correct, and all intraduct carcinomas are invasive from inception, there does appear to be a group of cases which behave much less aggressively than obvious invasive carcinoma. This emphasizes the value of the current work on the early detection of breast carcinoma.

The survival rate of men with carcinoma of the breast

ROBERT W. T. SLACK*

SUMMARY

The Cancer Register for the South-West Region of England has been used to examine the survival rate of men with carcinoma of the breast, and a comparison has been made with carcinoma of the breast in women. For all men with carcinoma of the breast the prognosis is worse than for all women, but comparing the prognosis by clinical stage, the difference between men and women is small. However, the survival rate in men under 65 years of age is appreciably better than for men over 65, and for older men the survival rate is considerably less than for women over 65.

CARCINOMA of the breast is rare in men, with an incidence of approximately 1 per cent of the incidence in women. The Registrar General's Statistics for England and Wales for 1972 show that the mortality rate from carcinoma of the breast was 3 per million for men compared with 443 per million for women. Notification of incidence for cancer of the breast occurs at a later age in men than in women; among 507 cases of carcinoma of the breast in men reported from the United States by Moss in 1964 the median age for notification was 64 years compared with 58 years among females. *Fig.* 1 shows a similar shift in age at death from carcinoma of the breast in men compared with women in this country, as recorded by the Registrar General for England and Wales in 1972.

The prognosis for carcinoma of the breast is generally believed to be poorer in men than in women (Vanderbilt and Warren, 1971), and Moss (1964) reported that in his series the 10-year survival rate for women was 49 per cent compared with 32 per cent for men. The discrepancy might be due to the relatively older age of the male patients, but even after correction is made for other causes of death, the female survival rate is 56 per cent compared with 43 per cent in males.

The stage of spread of the disease at the time of notification has an important effect upon survival in both men and women. In Moss's (1964) series in which the stage of the disease was classified as 'localized', 'regional' or 'distant', the prognosis was more favourable for women with localized disease or regional metastases but more favourable for men with distant metastases.

The relationship between the age of notification and the stage of the spread of disease in carcinoma of the male breast is not clear from the studies reported. The present investigation was undertaken to examine the survival rate in carcinoma of the male breast in the South-West Region of England and to find the effects of both age and clinical stage of the spread of the disease upon prognosis.

Patients and methods

The Cancer Register of the South-Western Regional Health Authority was examined and all the records of carcinoma of the male breast notified between 1960 and 1968 were extracted. Patients with carcinoma of the male breast who died from unrelated causes, including one who died from renal complications of carcinomatosis with a primary carcinoma in the kidney, were excluded. Preliminary examination of the whole series showed that no deaths from carcinoma of the male breast occurred more than 7 years after diagnosis; therefore in order to allow a full 7-year follow-up, all the patients presenting in 1968 were excluded. Patients were divided into 10-year age groups and into the four international clinical stage (TNM) groups (Copeland, 1969). Percentage survival rates were calculated by age and stage.

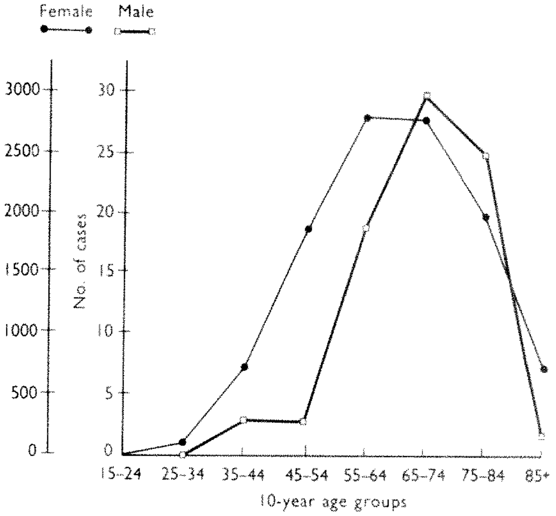

Fig. 1. Number of deaths from carcinoma of the breast in men and women recorded by the Registrar General for England and Wales in 1972.

Results

Between 1960 and 1968, 56 cases of carcinoma of the male breast were reported to the Cancer Registry of the South-Western Regional Health Authority. During that time 6000 cases of carcinoma of the female breast were notified, giving a male to female ratio of 0·93 per cent. After exclusion of 5 patients notified in 1968 and 13 patients who died from causes unrelated to carcinoma of the breast, 38 cases of carcinoma of the male breast were available for study.

Table I shows the numbers of patients according to age and clinical stage at the time of presentation of the disease.

Table II shows the percentage survival rate of the 36 patients in whom the stage of the disease was notified. In 2 patients the stage of the disease was unknown. *Fig.* 2 shows the percentage survival rate of the total group and of two subgroups, dividing the patients into Stages I and II and Stages III and IV for comparison.

Table III shows the percentage survival rate of the 38 patients divided into 10-year age groups. *Fig.* 3 shows the percentage survival rate in the whole group and in two age subgroups—those above and below 65 years.

Discussion

It has been thought that men with carcinoma of the breast have a worse prognosis than women, and this view was upheld by Somerville (1951), who considered that the unfavourable prognosis in men was due to the late presentation of the patients. Comparing the survival rate of men in the present series with that of women with carcinoma of the breast reported by Haagensen (1971), the 7-year survival rate of the total group of men of 37 per cent is indeed worse than the 10-year survival rate for women of 63 per cent. Unfortunately, in Haagensen's series the stage of the disease was determined by the Columbia Clinical Classification (Haagensen et al., 1963) into Stages A, B, C and D, and so the stages of disease in Haagensen's series are not strictly comparable with the international TNM staging used by the South-Western Regional Cancer Registry, but there is a close relationship between them (Handley, 1967). When the survival rate by stage is compared in men and women, only a small difference is found. Combining Stages I and II in men, the 7-year survival rate is 52·4 per cent, while in women, combining Stages A and B, the 10-year survival rate is 68 per cent. There is much less difference in survival rate for men and women presenting at the later stages of the disease. For Stages III and IV combined, the 7-year survival rate in men is 20 per cent, compared with a 10-year survival rate in women presenting with Stages C and D of 24 per cent. Thus, the overall poorer prognosis in men seems to be due to an excess of men presenting at a late clinical stage of the disease, as suggested by Somerville (1951).

When a comparison of survival rates of men and women with carcinoma of the breast is made by age a marked difference is found. For men under the age of 65 the 7-year survival rate is 52 per cent compared with a 10-year survival rate in women under 65 of 64 per cent. For men over 65 the 7-year survival rate is 18 per cent compared with a 10-year survival rate in Haagensen's (1971) series of 51 women over 65 years of 57 per cent. If there was evidence that a higher proportion of men over 65 presented with carcinoma of the breast at Stages III and IV than at Stages I and II, the explanation of the poor prognosis in older men might be found in the advanced stage of the disease. However, in the present series nearly equal numbers of patients with Stages III and IV were over and under 65, compared with 17 over 65 and 21 under 65 in the whole series (*see Table I*).

There seems little doubt that the prognosis for men over 65 with carcinoma of the breast is worse than the prognosis for younger men and that this difference is not explained by the later stage of the disease at presentation. An explanation of the poor prognosis in older men may lie in the decline of male hormones with age.

Operative cholangiography: a reappraisal based on a review of 400 cholangiograms

IRWIN FARIS, JAMES P. S. THOMSON, D. J. GRUNDY
AND L. P. LE QUESNE*

SUMMARY

In the period 1957–72, 426 patients were operated upon for calculous disease of the biliary tract. For various reasons pre-exploratory operative cholangiography was not performed in 26 patients, but in the remaining 400 patients this examination was the major determinant as to whether or not the common duct contained calculi, and hence required exploration. Analysis of this series of 400 patients shows that without operative cholangiography (a) ductal stones would have been overlooked in 16 of the 78 patients with stones in the common duct (4 per cent of the whole series; 20·5 per cent of those with stones in the common bile duct); (b) exploration of the common duct would have been required in a further 48 (15 per cent) of the 322 patients without stones in the common duct, giving a positive yield from operative cholangiography in 64 patients (16 per cent) in the whole series. Negative exploration of the common duct was performed in only 31 patients, that is 29 per cent of the patients whose duct was explored but only 7·8 per cent of the whole group.

The criteria by which an operative cholangiogram should be assessed were re-evaluated in the light of the findings in these 400 patients. In general the criteria of normality previously described were affirmed, and the following points established:

a. In the absence of a filling defect the diameter of the duct is the most important indication of the presence of a stone.

b. There is a statistically significant increase in the diameter of the common duct with age, and though not great this could, if neglected, give rise to error in the interpretation of the cholangiogram in younger patients.

c. Even within the overall normal range of duct diameter (<12 mm) the wider the duct, the greater is the chance of it harbouring a stone.

d. Impaired flow of contrast material into the duodenum is significantly related to duct diameter.

e. Impaired flow of contrast material into the duodenum and failure to delineate the terminal segment of the duct tend to occur together; they may occur in a duct free of stones and if they are the only abnormality the examination should be repeated after the inhalation of amyl nitrite.

This study confirms that operative cholangiography is the most accurate method at present available of determining whether or not the common duct contains a stone (or stones), and hence requires exploration.

OPERATIVE cholangiography is now a well-established technique. Many authors have shown that it detects stones in the common bile duct which would otherwise have been overlooked and reduces the number of unnecessary explorations (Schulenburg, 1969; Lawson and Gunn, 1970; Havard, 1970; McEvedy, 1970; Kakos et al., 1972). Despite this there is still opposition to its routine use.

This paper reviews our experience with this technique and allows a reappraisal of the features of a normal cholangiogram. The value of operative cholangiography in the diagnosis of stone in the common duct is compared with conventional clinical and operative indications.

Description of series

During the years 1957–72, 426 operations for gallstones were carried out in the clinical service of the senior author. There were 332 patients with stones in the gallbladder (GB) only and 94 patients with stones in the common bile duct (CBD); of the latter group, 12 patients had undergone a previous biliary tract operation. For a variety of reasons operative cholangiograms were not performed in 26 patients, leaving for analysis 400 patients with operative cholangiograms (GB group 322; CBD group 78). These patients were operated upon by a number of surgeons, many of whom were registrars in training.

The distribution of the age of the patients is shown in *Fig.* 1. The CBD group are significantly older than the GB group ($t = 5{\cdot}876$, $P < 0{\cdot}001$). There is no difference in the sex distribution between the two groups.

Pain was a symptom in 304 (94·6 per cent) patients of the GB group. In 7 patients cholecystectomy was performed concurrently with another procedure, and in 11 patients symptomless gallstones were removed at elective operation. There were 2 deaths following operation.

Methods

Operative cholangiography was performed through a catheter introduced into the cystic duct by the technique described by Le Quesne (1960). In patients with an apparently normal duct radiographs were taken following the slow injection of successively 2, 3 and 5 ml of 25 per cent sodium diatrizoate BP (Hypaque), but in those with an obviously dilated CBD the amount injected before the second and third exposures was increased. The CBD was judged to be

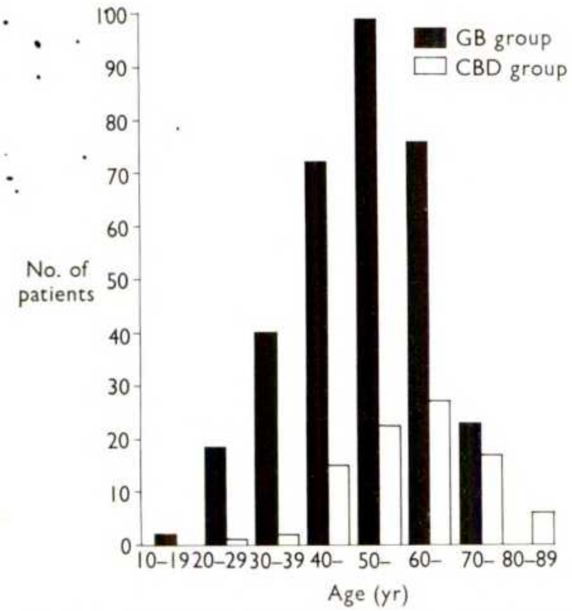

Fig. 1. Age distribution of the whole series (i.e. 426 patients). The age of patients with stone in the CBD is significantly greater than in those without ($t = 5{\cdot}876$, $P < 0{\cdot}001$).

normal if the cholangiogram fulfilled the following criteria (Le Quesne, 1960):

1. The diameter of the CBD as measured on the radiograph did not exceed 12 mm.
2. There were no defects within the CBD.
3. The narrow segment at the lower end of the CBD was clearly seen on at least one film.
4. There was flow of contrast medium into the duodenum on the first film; provided that the examination was in all other respects normal, flow seen initially on the second film was accepted as normal.

Fig. 2 shows an example of a normal operative cholangiogram fulfilling these criteria.

At the time of the patient's discharge from hospital the relevant clinical and radiological information was entered on a card. These cards provided the data for this survey.

In the analysis that follows the clinical and operative criteria for exploration of the CBD are defined as:

1. Jaundice, present or in the recent past.
2. Operative finding of a dilated CBD or palpable stones within the CBD.
3. The presence of multiple stones (three or more) within the gallbladder.
4. Demonstration of a defect in the CBD on a preoperative intravenous cholangiogram. This investigation was performed on 130 patients in the GB group and on 57 patients in the CBD group.

The frequency of occurrence of these criteria is shown in *Tables I* and *II*.

Results

The following analysis is based on the 400 patients upon whom an operative cholangiogram was performed.

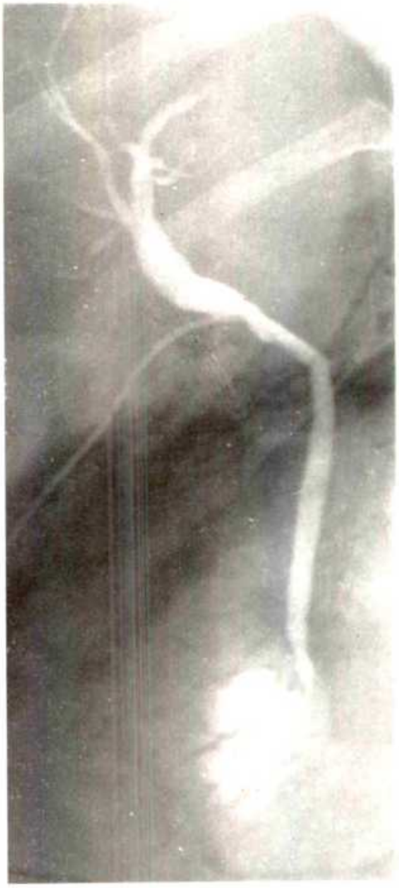

Fig. 2. First film from a normal operative cholangiogram. Note the free flow of contrast material into the duodenum, the visualization of the whole of the narrow segment and the absence of filling defects. This picture is slightly enlarged from the original radiograph, in which the diameter of the common duct was 9 mm.

Table I: FREQUENCY OF CONVENTIONAL CRITERIA FOR EXPLORATION OF THE CBD

Criteria	GB group No.	GB group %	CBD group No.	CBD group %
Jaundice, present or recent past	46	14	49	63
Dilated duct at operation	15	5	54	69
Stone palpable at operation	2*		50	64
Multiple stones palpable in gallbladder (3 or more)	173	55	34	44

* These calculi were found to be impacted at the lower end of the cystic duct.

Table II: INCIDENCE OF A DEFECT SHOWN IN THE CBD ON INTRAVENOUS CHOLANGIOGRAPHY

Intravenous cholangiogram	GB group No.	GB group %	CBD group No.	CBD group %
Number performed	130	40	57	73
Number showing defects in CBD	1		33*	

* Thus, this preoperative investigation only indicated the presence of calculi in the CBD in 58 per cent of the patients.

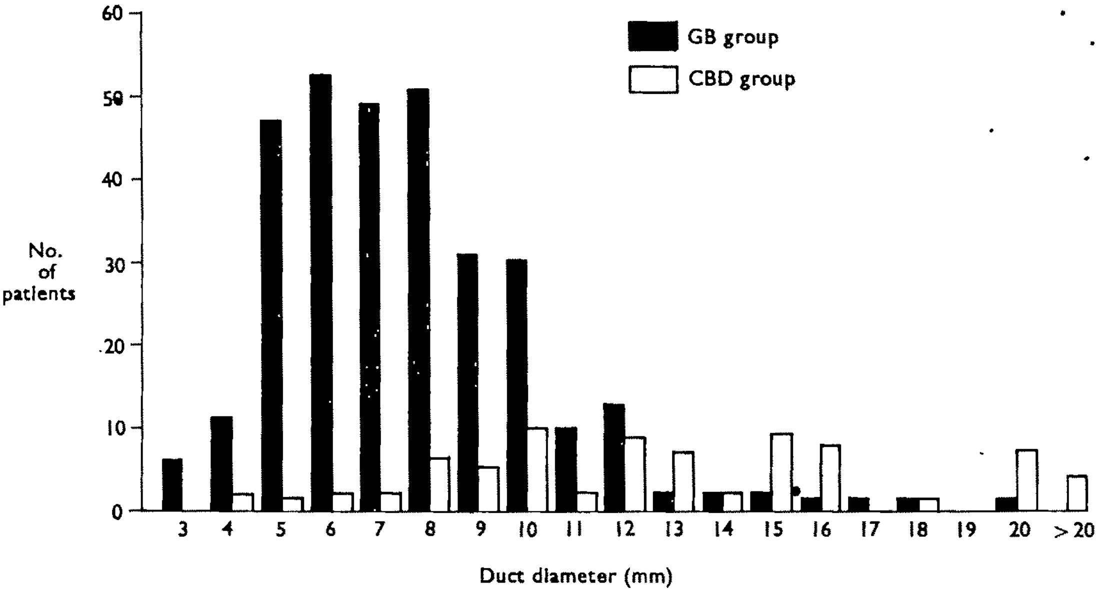

Fig. 3. Distribution of the duct diameter in the 400 patients who had operative cholangiography. The diameter of the duct in the CBD group was significantly larger than the GB group ($t = 10{\cdot}09$, $P<0{\cdot}001$).

Table III: OVERALL VALUE OF OPERATIVE CHOLANGIOGRAPHY

	GB group			CBD group		
		Cholangiogram			Cholangiogram	
	Total	Normal	Abnormal	Total	Normal	Abnormal
No clinical or operative indications for exploration of CBD	249	243	6*	16	0	16
Clinical and/or operative indications for exploration of CBD	73	53†	20*	62	0	62

* Negative exploration of CBD. † CBD explored in 5 cases.

Assessment of overall value of cholangiography

The overall value of the routine performance of this investigation can be gauged from *Table III*. In 16 patients (4 per cent) the cholangiogram revealed the presence of an unsuspected stone in the duct. In 53 patients in whom there were clinical and/or operative indications of a stone in the duct, the cholangiogram revealed a normal duct. In 5 of these 53 patients, despite the normal cholangiogram, the common duct was explored, because of a recent history of jaundice in 4, and the finding on prior intravenous cholangiography of an apparently dilated common duct in the fifth. Thus, in 64 patients [16+(53−5)] (16 per cent) the operative cholangiogram gave positively useful information, resulting in the correct decision being made as to whether or not the duct should be explored, and in a further 5 patients (making 17 per cent in all) it gave the correct information which was not acted upon for the reasons stated above.

In 26 patients the cholangiogram was interpreted as indicating the presence of a stone, but a stone was not found on exploration of the duct (i.e. false positives 6·5 per cent). Of these 26 patients, 9 had what was thought to be a filling defect. The remaining 17 patients had abnormalities of one or more of the other criteria, commonly a failure in flow. Of these 17, 13 had in addition clinical and/or operative indications for exploration of the duct.

In the whole group the CBD was explored in 109 patients (27·3 per cent), and in 78 (71·5 per cent) of these, stones were found in the CBD.

Analysis of cholangiograms

Duct diameter: The distribution of the diameter of the duct is shown in *Fig*. 3. Common bile ducts which contained stones were significantly larger than those which were stone-free ($t = 10{\cdot}09$, $P<0{\cdot}001$).

In the GB group (i.e. patients with a normal CBD) there was a significant correlation between duct diameter and age ($r = 0{\cdot}27$, $P<0{\cdot}001$). This is shown in *Fig*. 4 on which the 95 per cent tolerance limits are shown in addition to the regression line. The age and duct diameter of patients in the CBD group are plotted in relation to these boundaries in *Fig*. 5. Whilst 46 patients (59 per cent) with stones in the CBD had a dilated duct, it is to be noted that 32 (41 per cent) of the patients with stones in the CBD have duct diameters within the 95 per cent tolerance limits for stone-free ducts. Analysis of these figures in greater detail (*Fig*. 6) shows the percentage chance of having a stone in the CBD for a duct of given diameter. This relationship between duct diameter and the chances of the duct containing a stone is highly significant ($r = 0{\cdot}9698$, $P<0{\cdot}001$) and is unaffected by correction for age. It can be seen, for example, that a duct at the upper limit

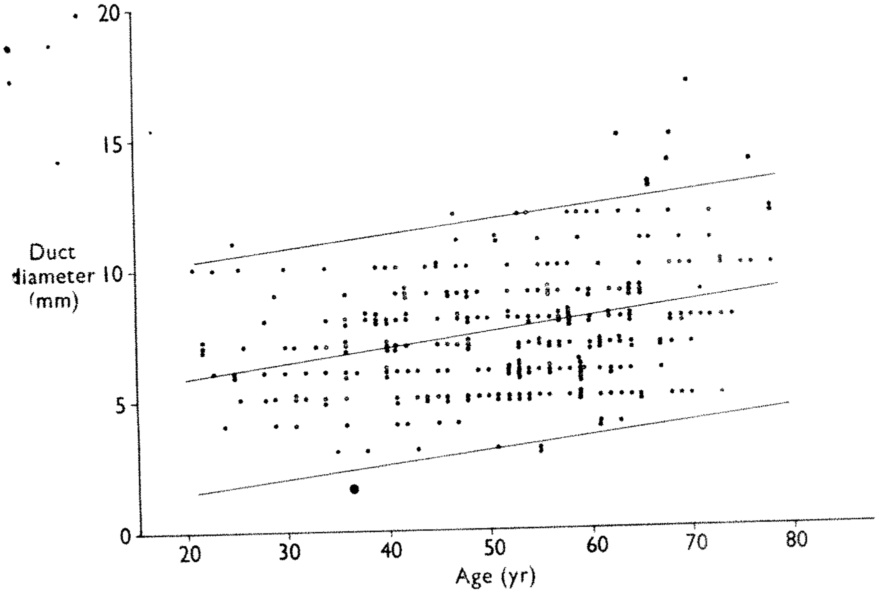

Fig. 4. Regression line and 95 per cent tolerance limits for the correlation between age and duct diameter for the GB group ($r = 0{\cdot}27$, $n = 307$, $P < 0{\cdot}001$). The diameter of the duct was not recorded in 15 patients of this group.

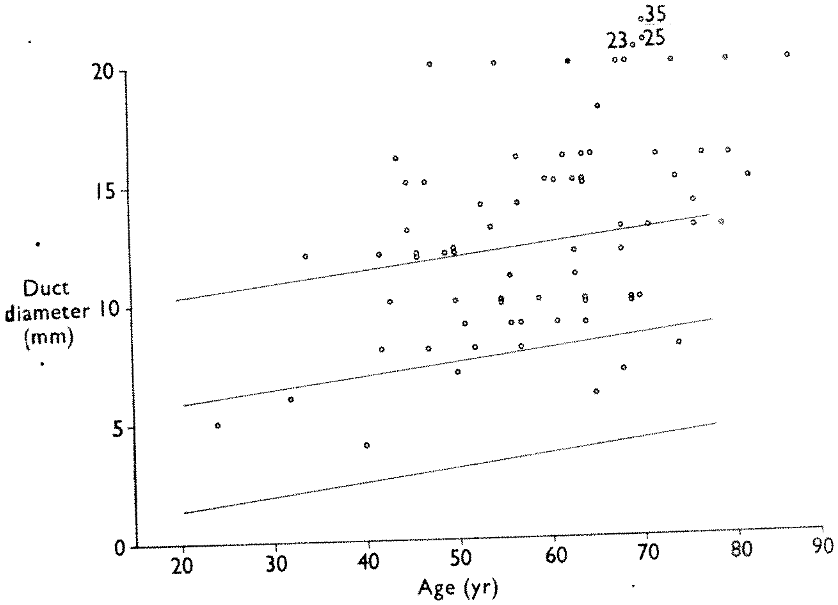

Fig. 5. Each point represents the age and duct diameter of the 78 patients in the CBD group. These have been plotted in relationship to the regression line and 95 per cent tolerance limits derived in *Fig.* 4.

of the normal range (11–12 mm) has a 32 per cent chance of containing a stone.

Filling defects: Filling defects were demonstrated in 67 (86 per cent) of the patients with stones in the CBD. However, in 11 patients (14 per cent) with a stone in the duct a defect was not seen and the correct diagnosis made from the other criteria described. As previously mentioned, in 9 patients in the GB group a filling defect was seen on the cholangiogram but no stone was found on exploration of the duct; review of these films suggests that in each instance the defect was caused by an air bubble.

Demonstration of the narrow segment: The narrow segment was seen less frequently in patients with stones in the CBD than in those without (*Table IV*) ($\chi^2 = 107$, $P \leqslant 0{\cdot}001$). The segment was not seen in 7 per cent of the GB group and in 55 per cent of the CBD group.

Flow into the duodenum: *Table V* indicates the radiograph on which flow into the duodenum was first seen.

There was a distinct difference between the two groups in the time of appearance of contrast medium in the duodenum. Further analysis showed that there was also a highly significant relationship between duct diameter and delay in flow into the duodenum ($r = 0{\cdot}5426$, $n = 377$, $P \leqslant 0{\cdot}001$), a large duct being associated with delayed flow into the duodenum.

Use of amyl nitrite: A common cause of a false positive cholangiogram (i.e. one apparently indicating the presence of a stone in the CBD) is a failure to demonstrate the narrow segment and delayed flow of contrast into the duodenum. Insufflation of amyl nitrite into the airway followed by repetition of the cholangiogram can resolve some of these difficulties (Le Quesne, 1960). This technique was used in 13 patients in whom the CBD was of normal calibre and no defects were seen but in whom there was no flow of contrast into the duodenum and no demonstration of the narrow

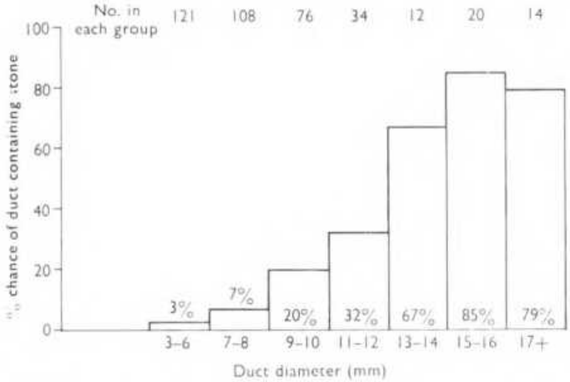

Fig. 6. Percentage chance of a duct of given diameter containing a stone.

No flow seen	18	6	31	40
Information not available	23	7	Nil	

Eleven of the 18 patients in the GB group in whom no flow was seen had a repeat examination after amyl nitrite (*see* text revealing a duct in all respects normal. Note that in approximately 80 per cent of the GB group flow was first seen in the first or second film.

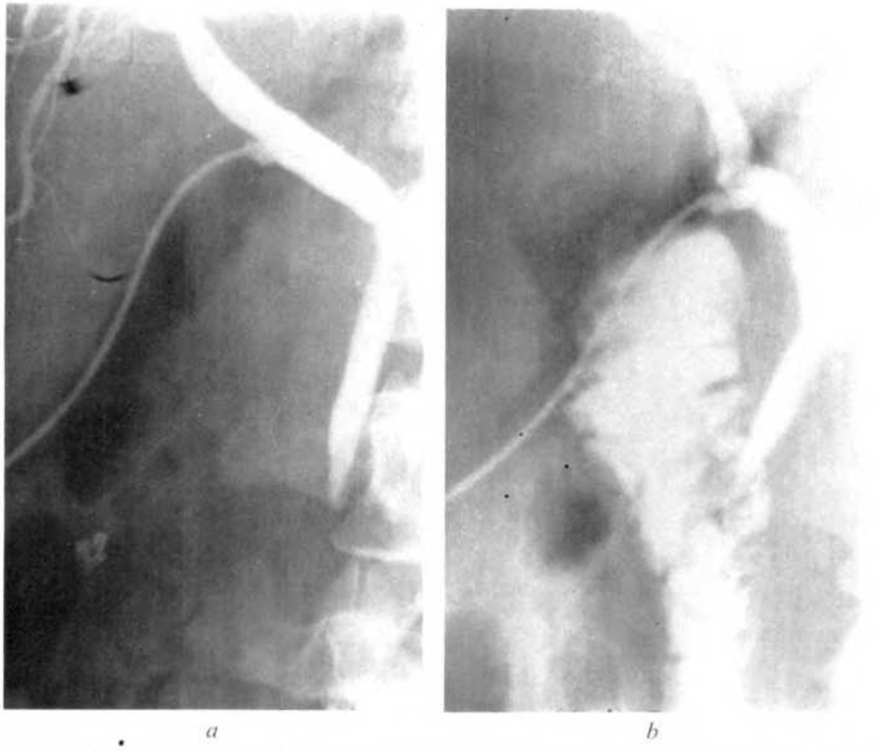

Fig. 7. *a*, One of the three cholangiograms from a series in which the only abnormality was absence of flow, with failure to demonstrate the narrow segment. *b*, Repetition of the examination after the inhalation of amyl nitrite showed free flow of the contrast material and a cholangiogram in all respects normal.

segment. In 11 of these patients the second cholangiogram was normal (*Fig.* 7) and accordingly an exploration was not performed; in 2 patients stones were demonstrated in the CBD.

Discussion

Overall value

This series differs from several other published reports of this technique in that the operations were performed by a number of surgeons including registrars of varying experience. This is important as it is at least possible that the good results obtained in many personal series depend on the interest of the observer, and may not be reproduced when the technique is adopted by others.

The major aim of operative cholangiography is to add precision to the diagnosis of stone in the CBD. This should result in: the detection of stones in the CBD which would otherwise have been overlooked; a reduction in the number of normal ducts explored.

In 16 (20·5 per cent) patients with stones in the CBD there were neither clinical nor operative indications for choledochotomy, the diagnosis being made solely on the basis of an abnormal cholangiogram. The negative exploration rate is commonly expressed as a percentage of the number of duct explorations performed. In this series the rate was 29 per cent. This compares with a negative exploration rate reported by other authors using cholangiography of 28–44 per cent (Wheeler et al., 1970; Kakos et al., 1972; Way et al., 1972; Glenn, 1974), and 46–58 per cent without cholangiography (Schofield and Macleod, 1966; Wheeler et al., 1970). We were unable to demonstrate a fall in the negative exploration rate with time, probably because of the number of surgeons who performed the operations in this series.

The biggest single cause of a false positive cholangiogram is the presence of air bubbles; these can be avoided by scrupulous attention to technical details, and the greatest care must be taken to avoid their introduction into the duct. The most severe difficulties in interpretation occur when with a duct of normal diameter, in the absence of filling defects, there is no flow of contrast into the duodenum and there is no demonstration of the narrow segment. These appearances are due to contraction of the muscle surrounding the lower end of the duct. This may be caused by a small stone in the duct, but is more commonly due to other factors such as the variety of pharmacological agents used in anaesthesia. From the evidence of this study it is clear that repetition of the examination after the inhalation of amyl nitrite is a valuable method of clarifying the situation. In fact this technique was rarely, if ever, used by registrars, and if it had been it would probably have resulted in avoidance of exploration of a number of ducts which were in fact explored solely because of abnormalities of flow or failure to demonstrate the terminal narrow segment. If there is still doubt after the second examination it need hardly be said that the common duct must be explored.

Forty-eight of the 135 patients (36 per cent) who had clinical or operative indications for exploration of the CBD were saved this unnecessary procedure by the demonstration of a normal operative cholangiogram. It is arguable that in some of these patients a stone in the duct was in fact missed. However, close follow-up of patients early in this series (Chapman et al., 1964) and the reports of other authors (Ferguson and Estes, 1967; Glenn, 1974) indicate that this is most unlikely, and that an operative cholangiogram fulfilling the criteria set out earlier can be relied upon with confidence as evidence of a normal stone-free duct. In view of this it is now our practice not to explore the duct of patients with a history of jaundice, even if recent, if the operative cholangiogram is in all respects normal.

The normal cholangiogram

This study has allowed us to reassess our criteria of the normal cholangiogram. The increase in duct size with age has long been suggested but not clearly defined. We have demonstrated a significant increase in duct diameter with age. This may be important in a young patient in whom a 10- or 11-mm diameter CBD may be abnormally dilated. However, the duct diameter is not an absolute indicator of the presence of a stone in the CBD, since, from *Figs.* 4 and 5, it can be seen that two-fifths of the patients with CBD stones have ducts of normal calibre. In addition, *Fig.* 6 shows that there is no upper limit of duct diameter above which the incidence of stones suddenly increases.

The analysis confirms the validity of current criteria of the flow of contrast medium into the duodenum and the demonstration of the terminal narrow segment of the common bile duct. There is no difference in the discrimination obtained if these criteria are considered separately or in combination. The demonstration that delay in flow of contrast into the duodenum is directly proportional to the duct diameter may indicate inadequate filling, or it may be due to obstruction which results in failure of flow and dilatation of the duct. In this regard an injection of contrast medium at standard pressure (Daniel, 1972), rather than of standard volume, might distinguish between these causes and represent an improvement in technique.

Evaluation of conventional indications

The results of this study emphasize the inadequacy of conventional indications in the diagnosis of stone in the CBD. Analysing the whole group of 400 patients it was found that a patient who gives a history of jaundice is as likely to have stones in the gallbladder only as he is to have a stone in the common bile duct (*Table I*). Way et al. (1972) found jaundice more commonly associated with stones in the CBD, but when jaundice was the only indication for exploration stones were found in the CBD in only 6 of their 17 patients.

It is frequently recommended that the CBD should be explored in all patients with multiple stones in the gallbladder. The evidence from this study does not support this assertion. (In this analysis 'multiple stones' means more than 3, and if the phrase 'a few stones' was used the patient was considered not to have multiple stones.) As will be seen from *Table I* there was no significant difference in the incidence of multiple stones in the two groups, a finding in conformity with that of Mullen et al. (1972).

Intravenous cholangiography may be useful in demonstrating a stone in the CBD. In the 57 patients in the CBD group in whom this examination was performed a stone was demonstrated in 33, but in 24 patients the preoperative examination was considered normal. This confirms the finding of Grundy et al. (1972) that an operative cholangiogram is more accurate than intravenous cholangiography in the diagnosis of stone in the common duct.

This study also reaffirms that operative assessment (by inspection and palpation) of the CBD is not a sufficiently sensitive method of detecting stones. In this series only two-thirds of the stones in the CBD were palpable. It was anticipated that increasing reliance on the operative cholangiogram would result in less careful palpation of the duct, but the number of stones felt in this series (64 per cent) is similar to that in Daniel's (1972) series where the primary method of diagnosis was careful palpation. Determination of the duct size at operation may be difficult and it should be remembered that two-fifths of ducts containing stones were of normal calibre.

Conclusion

This study of 400 patients undergoing cholecystectomy with operative cholangiography confirms that this method of examination is the most reliable investigation available for determining whether or not the duct contains a stone or stones. Further, the study reaffirms the criteria of normality previously described, and shows that the greater the diameter of the duct as seen on cholangiography, the greater the chance of it harbouring a stone, whether or not the duct diameter is within normal limits.

Carcinoma of the duodenum: its preoperative diagnosis

K. SATAKE, M. SOWA, K. YAMASHITA, K. KAMINO,
H. KINOSHITA, M. KATO AND K. UMEYAMA

SUMMARY

Carcinoma of the duodenum, although uncommon, can be diagnosed by direct visualization, photography of the tumour and biopsy by the fibre-duodenoscope. The duodenoscopic examination may not only distinguish carcinoma of the duodenum from pancreatic carcinoma, ampullary carcinoma and secondary tumour from an adjacent organ but will also enable a correct diagnosis to be made early in the course of the disease.

It is therefore suggested that duodenoscopy and biopsy will increase the resectability and 5-year survival rate.

CARCINOMA of the duodenum is an uncommon disease and most of our knowledge is based on necropsy studies (Eger, 1933; Willis, 1948). In the past decade only a small number of individual cases with satisfactory results following treatment have been reported (Warren et al., 1962; Cartese and Cornall, 1972).

Early diagnosis of this disease is extremely difficult. However, the development of the fibre-duodenoscope for duodenal observation has opened a new diagnostic field and made possible early detection and accurate diagnosis of this disease before operation.

In this paper 2 new cases are presented and discussed together with cases reported in the literature, particular attention being paid to those with an accurate preoperative diagnosis. The 2 cases reported here were diagnosed as duodenal tumour by upper gastro-intestinal examination, and the diagnosis was confirmed by duodenoscopy and biopsy.

Case reports

Case 1: A 64-year-old man complained for a month of malaise, weight loss and dull back pain. He had vomited three or four times a day for weeks but gave no history of dysphagia, haematemesis, melaena or jaundice. About a year previously he had undergone gastrectomy (Billroth I) for gastric ulcer at another hospital. Subsequently he had been quite well and free of symptoms until the present episode.

On admission to Osaka City University Hospital the patient was thin, appeared pale and chronically ill but no jaundice was noted. Abdominal examination was essentially normal except for the upper median gastrectomy incision, and rectal examination was normal.

Laboratory investigations on admission revealed a haemoglobin of 8·0 g/100 ml with a red blood cell count of 3 160 000/mm³. Serum electrolyte levels were within normal limits as were the serum glutamic oxalo-acetic transaminase, serum bilirubin and alkaline phosphatase values. The total serum protein value was 6·0 g/100 ml and albumin 3·6 g/100 ml. Stool samples were strongly positive for occult blood. Examination of the upper gastro-intestinal series showed a 2 × 3 cm filling defect of the distal duodenum with slight dilatation proximally (*Fig.* 1). Duodenoscopic examination revealed normal stomach and proximal duodenum, but a well-localized 2 × 3-cm tumour with ulceration in its centre was found in the third part of the duodenum. Biopsy of the tumour showed a well-differentiated adenocarcinoma.

An extended pancreatoduodenectomy was performed with removal of the anastomotic region of the stomach, the duodenum, head and body of the pancreas and regional lymph-nodes. No distant lymph node swelling was found. Reconstruction was accomplished by suturing the common bile duct to the proximal end of the jejunum, implanting the pancreatic duct by direct suture of the pancreas and jejunum in an end-to-side fashion and constructing a gastrojejunostomy.

The pathologist reported that section of the tumour showed a well-differentiated adenocarcinoma with extension through the mucosa to the muscle layer but not to the serosa (*Figs.* 2, 3). Section of regional lymph nodes showed no involvement.

Fourteen months after discharge there was no evidence of recurrence and the patient was well and working.

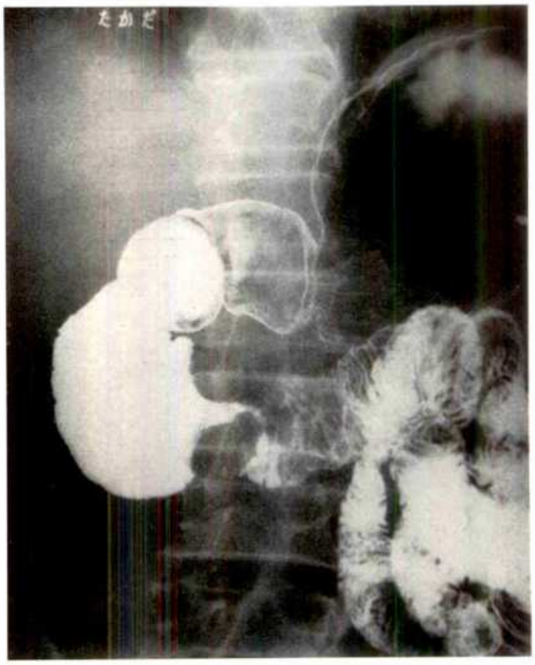

Fig. 1. *Case* 1. Upper gastro-intestinal film showing a 2 × 3-cm filling defect in the third part of the duodenum with slight dilatation proximally.

Case 2: A 35-year-old man, complained of crampy epigastric pain for 7 months. A month prior to his admission his symptoms had increased in severity, with progressive and continuous pain which radiated to his back. He had been treated for about 6 months at another hospital following diagnosis of duodenal ulcer but had shown no improvement.

On admission to Biwako Hospital he was thin and chronically ill. He stated that over the past 2 months he had lost about 7 kg in weight. Abdominal examination revealed tenderness

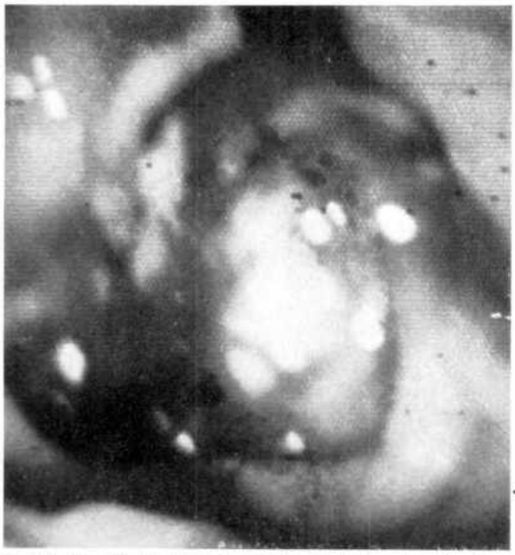

Fig. 4. *Case* 2. Endoscopic photograph showing the tumour and ulceration in the duodenum.

in the epigastrium with muscle rigidity, and a 4 × 5-cm tumour-like resistance was palpable in the epigastrium. Rectal examination was normal.

Laboratory investigations on admission revealed a haemoglobin level of 11·0 g/100 ml with a red blood cell count of 3 290 000/mm^3. Serum electrolyte levels were within normal limits. The serum glutamic oxalo-acetic transaminase was 110 Karmen units and the alkaline phosphatase was also slightly elevated, but the serum bilirubin was within normal limits. The total serum protein value was 6·6 g/100 ml and albumin 3·9 g/100 ml. Stool samples were strongly positive for occult blood.

Upper gastro-intestinal examination showed an ulcerating growth, 2 cm in diameter, in the third portion of the duodenum, and there was a 3 × 4-cm filling defect around the ulceration. Carcinoma of the duodenum was suspected. The results of duodenoscopy revealed a 6 × 7-cm tumour with deep ulceration in the centre of the tumour (*Fig.* 4). Biopsy of the tumour showed a poorly differentiated adenocarcinoma (*Fig.* 5), and primary carcinoma of the duodenum was diagnosed.

An extended pancreatoduodenectomy was performed, with removal of the antrum of the stomach, the duodenum, contiguous lymph nodes near the coeliac axis, fat and lymph nodes near the superior mesenteric artery and vein and lymph nodes over the aorta underlying the third and fourth portions of the duodenum. Reconstruction was accomplished in the same manner as in *Case* 1.

The pathologist reported that sections of the tumour showed a poorly differentiated adenocarcinoma with extension through all layers of the bowel wall, including the serosa. Five of the regional lymph nodes examined showed no involvement.

Three months after discharge the patient was symptom-free and there was no evidence of recurrence.

Discussion

In necropsy studies the incidence of carcinoma of the duodenum is 0·01–0·04 per cent (Eger, 1933; Willis, 1948). It comprises 0·3 per cent of all gastro-intestinal carcinomas and 45–47 per cent of those of the small intestine (Eger, 1933; Hancock, 1970).

Descriptions of the distribution of carcinoma of the duodenum state that 59·2 per cent of the tumours are periampullary and also that supra-ampullary lesions (22·5 per cent) are more common than infra-ampullary (18·3 per cent) (Ebert et al., 1953; Brenner, 1955; Maurer, 1968; Cleator, 1970). By contrast, Resnik and Cooper (1958) have reported 17 per cent as periampullary with the remainder being evenly distributed above and below the ampulla.

The age distribution has its peak in the fifth and sixth decades but the lesion can occur as early as the second decade. Most series report an equal incidence in both sexes (Kenefick, 1972).

The most common symptoms and signs are those of gastro-intestinal obstruction, abdominal discomfort and pain, weight loss and chronic blood loss leading to anaemia. Burgerman et al. (1956), reviewing 31 cases of duodenal carcinoma, found the incidence of symptoms to be as follows: abdominal pain 74 per cent, anaemia 55 per cent, melaena 29 per cent, haematemesis 23 per cent, jaundice 23 per cent, abdominal mass 19 per cent. In the present cases weight loss and anaemia were the main symptoms in *Case* 1, and abdominal pain and weight loss in *Case* 2. Neither patient was jaundiced and the confirmed diagnosis in both cases was infra-ampullary carcinoma. Each case had repeatedly positive occult blood in the stool. This suggested that chronic haemorrhage and iron-deficiency anaemia are the important clinical symptoms. Early clinical diagnosis of carcinoma of the duodenum is extremely difficult, especially for carcinoma in the infra-ampullary region. It relies entirely on suspicion and awareness of the condition. Initial symptoms are vague, and the more severe symptoms such as obstruction, gastro-intestinal haemorrhage and perforation are late features. However, early diagnosis is essential if the poor prognosis is to be improved.

Upper gastro-intestinal examination may not help in diagnosis as its accuracy is limited, and the third part of the duodenum especially is difficult to visualize and may need special positioning. This causes further delay in diagnosis. In a recent report routine upper gastro-intestinal examination diagnosed only about 64·6 per cent of the cases correctly (Sakker and Ware, 1973). In the present series upper gastro-intestinal examination in *Case* 1 revealed the tumour (2 × 3 cm), and in *Case* 2 ulceration in the third part of the duodenum. Usually tumours of the duodenum of more than 1 cm are demonstrable. When this technique is unsatisfactory, hypotonic duodenography is advisable. However, in the present cases the upper gastro-intestinal examinations alone revealed the lesions, although the nature of the growths could be confirmed by biopsy.

The development of duodenoscopy should help to diagnose carcinoma of the duodenum by direct visualization, photography of the tumour of the duodenum and biopsy. Duodenoscopy will not only distinguish carcinoma of the duodenum from pancreatic carcinoma, ampullary carcinoma and secondary tumour from adjacent organs but also diagnose these abnormalities at an early stage. In the present series diagnosis of primary carcinoma of the duodenum was confirmed by duodenoscopy and biopsy. It is suggested that duodenoscopy and biopsy are of great value in obtaining an accurate diagnosis before operation.

The choice of treatment depends on the extent of the lesion and the general condition and age of the patients. Pancreatoduodenectomy should be performed when feasible as this gives the best results. Operability of this disease has increased from 50 per cent (Resnik and Cooper, 1958) to 93·4 per cent (Serrano and Mcpeak, 1966; Sakker and Ware, 1973) and resectability of the tumour has also increased from 41 per cent (Serrano and Mcpeak, 1966) to 61·7 per cent (Sakker and Ware, 1973). However, the 5-year survival rate in this disease is still low. In *Case* 1 a radical operation was carried out satisfactorily because there was no extension of the carcinoma through the duodenum and no lymph node metastases. In *Case* 2, the tumour was larger than in *Case* 1 but a radical operation was performed because there was no invasion of the carcinoma through the duodenum and no lymph node metastases. Both patients have been well and free of symptoms for 14 months and 3 months respectively.

Conclusions

In the diagnosis of carcinoma of the duodenum careful radiological examination is a very important procedure. Duodenoscopy and biopsy are the most reliable methods to confirm the duodenal pathology.

The cases reported here emphasize that duodenoscopy and biopsy are of great value in confirming the diagnosis and in understanding the state of the disease before operation. It is suggested that duodenoscopy and biopsy will increase the resectability and the 5-year survival rate. In the near future the early detection of carcinoma of the duodenum by this method may become practical.

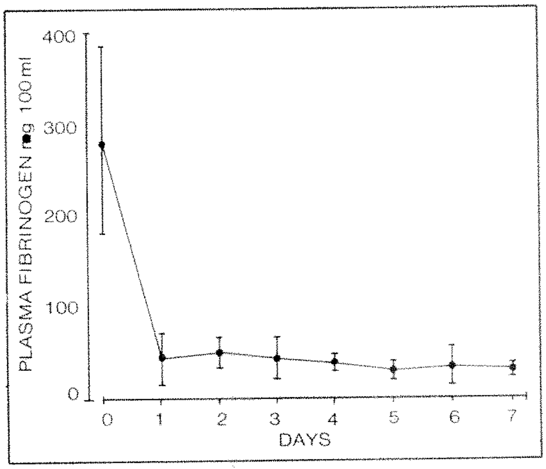
A new concept in the control of occlusive vascular disease.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR. (1971). Thromb Diath Haemorrh. 45, 43.

Its name is Arvin.

This unique drug is now available to specialists, for routine anticoagulant therapy, and to researchers into thromboembolic disorders.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

The consistent does-effect relationship of Arvin allows simple and precise methods of control.

On this basis, we recommend Arvin wherever controlled therapeutic defibrination is desirable.

Full prescribing information, and clinical evidence from studies on the broad range of thromboembolic disorders, are available on request.

Your hands are your most important instruments-
it pays to take care of them

The obvious fact that a surgeon's hands are of prime importance to his work was borne in mind when 'Hibiscrub' was formulated. 'Hibiscrub' is designed to keep hands healthy, even after repeated use.

However, the prime importance of a handwash is effectiveness: rapid prolonged bactericidal action against skin bacteria is assured by the presence of the well-proven antiseptic 'Hibitane'.

"These studies have shown that a 4% chlorhexidine detergent solution ['Hibiscrub'] is a potentially outstanding addition to the small list of detergent-disinfectant preparations for the hands of surgeons and nurses, with a greater immediate effect than that obtained with the hexachlorophane or even the iodophor preparations."
British Medical Journal, (1973), 1, 510.

Clinical features of the degenerate meniscus with the results of meniscectomy

JONATHAN NOBLE*

SUMMARY

A series of 172 patients with an unambiguous diagnosis of horizontal cleavage lesion is reviewed, the average duration of which was 4½ years. Although all the patients complained of pain, night pain and mechanical instability were not invariable. Joint line tenderness was the commonest physical sign. Whereas all but 7 per cent were either 'cured' or 'improved', nearly half the patients had persistent complaints, usually pain. The objective physical findings at review frequently failed to correspond with patients' opinions of their knees. Recovery after meniscectomy may be slow.

In Smillie's (1970a) experience a horizontal cleavage lesion is the commonest single meniscus tear. Reference to other literature regarding meniscus pathology suggests that horizontal cleavage is neglected as a diagnostic entity. Smillie (1970b) has described the typical signs and symptoms, but their incidence has not been quantified. Noble and Hamblen (1975) discovered this lesion in at least one meniscus in 60 per cent of an elderly group of random autopsy subjects, and concluded that not all people possessing such a lesion were likely to have had complaints from it. All patients who were recorded as having had a horizontal cleavage lesion removed in the University Department of Orthopaedic Surgery, Edinburgh, between 1963 and 1968 have been reviewed to determine the incidence of clinical features and to assess the results of meniscectomy.

Patients

One thousand two hundred and twenty-five patients underwent meniscectomy in this department between 1963 and 1968, from whom there were 172 patients with an unambiguous operative diagnosis of horizontal cleavage lesion. This included menisci with a parrot beak tear and horizontal cleavage and also frayed degenerate menisci with gross horizontal tearing. One hundred and fifty-five patients were still available for follow-up, of whom 113 (74 per cent have been recently reviewed for this study (*Table I*). A further 27 returned a questionnaire regarding their pre- and postoperative symptoms, so that we had information from 92 per cent of the available patients, 8 per cent apparently ignoring all communications. Thirteen patients were untraceable or had emigrated, 5 had died before review and in 2 patients review was precluded by further surgery.

Simultaneously, 100 consecutive patients who were admitted for meniscectomy were asked preoperatively if they experienced night pain. Their reply was then correlated with the pathology of the excised meniscus.

Findings

Age and occupation

Fig. 1 shows a predominantly middle-aged series although one-third were below the age of 40 and 2 patients were in their teens. Twenty-eight per cent of the males were coal miners.

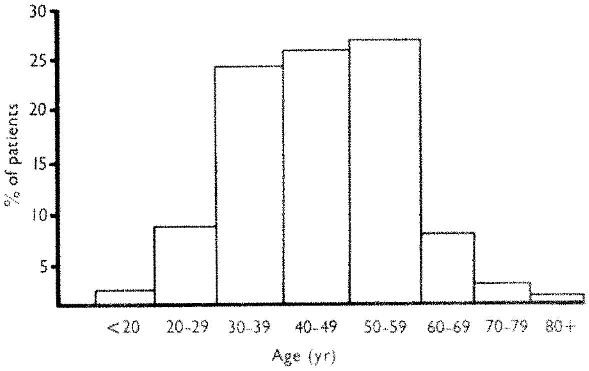

Fig. 1. Age distribution.

Table I: RESULTS OF REVIEW 1969–70 AND 1974

Patients:	Examined	No.: 113 (74%)
	Completed questionnaire	27 (18%)
	Ignored contact	12
	Total available	152 (92%)
	Died before review	5
	Surgery excluded	2
	Untraceable/emigrated	13
	Total unavailable	20
	Total no of patients	172

Duration of follow-up and onset

The duration of follow-up is shown in *Fig.* 2, the overall average for which was 4½ years. The onset of symptoms was insidious in 49 per cent.

Sex and side distribution

In this clinical series the incidence of horizontal cleavage lesions in males and females and on the medial and lateral sides has been compared with the same parameters in the autopsy series (Noble and Hamblen, 1975) (*Fig.* 3). In the clinical study males

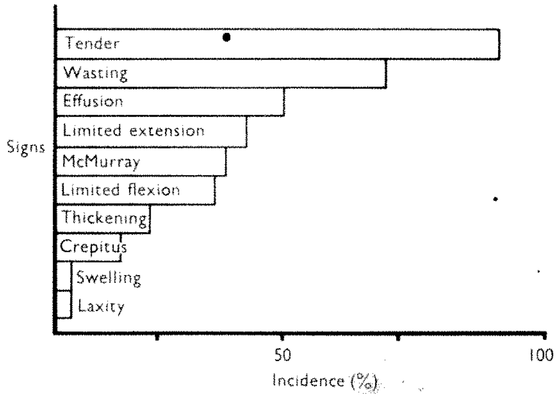

Fig. 5. Incidence of physical signs.

and medial lesions outnumbered females and lateral lesions respectively by 5 : 1, whereas in the autopsy series the male : female ratio approached equality, and the ratio of medial to lateral lesions was only 2 : 1.

Symptoms

The incidence of symptoms is shown in *Fig.* 4, pain being invariable. Seventy per cent complained of night pain, 62 per cent of whom said it was brought on or worsened by their knees touching or rubbing together Two-thirds of these patients separated their knees in bed by means of a pillow. Some patients only had night pain on turning over in bed, or when lying recumbent and 13 per cent put a pillow behind rather than between their knees to keep them in flexion. Fifty-seven per cent mentioned knee swelling, 45 per cent experienced instability or a feeling of insecurity, particularly on walking over uneven ground, and 32 per cent complained of locking.

Two-thirds of the 100 patients questioned just before meniscectomy complained of night pain, including several who were found to have bucket handle tears. Alternatively, not all those who had a horizontal cleavage lesion had previously complained of night pain.

Physical signs

Fig. 5 shows that the commonest physical sign was joint line tenderness, elicited in 86 per cent, whereas the region of the joint line was noted to be thickened in 22 per cent. Two-thirds of the cases had quadriceps wasting and half had an effusion, whilst limitation of extension and/or flexion was recorded in rather less than half the patients.

Results

Almost half of the patients examined or questioned (*Fig.* 6) still had pain, although in most it had been improved by meniscectomy. Twenty-three per cent had night pain, all of whom exhibited joint line tenderness. Sixteen per cent complained of stiffness and another 16 per cent of instability although none complained of locking. One-third of those seen on review had crepitus (*Fig.* 7) although often slight; this was the commonest sign on review. Approximately 20 per cent were noted to have wasting, joint line tenderness, effusion or limitation of flexion and/or extension. Fifteen per cent demonstrated an asymmetrical laxity of the anterior cruciate ligament, which had only been recorded preoperatively in 2 per cent. Twenty-four per cent of those reviewed had an entirely normal knee. However, the objective physical findings did not always match patients' opinions of their knees. One-third of those with an apparently normal knee had complaints, whereas there were other patients who regarded themselves as 'cured' but were found to have significant physical signs.

Although 65 per cent of the patients left hospital in less than 2 weeks, 91 per cent lost more than a month off work following surgery, including several housewives unable to resume full domestic duties. Nine patients, 8 of them coal miners, felt that their knee condition had brought about a change or loss of job.

Seven patients are now dead, this being unrelated to meniscectomy in all but the case of a 56-year-old woman who died of a pulmonary embolus 10 weeks postoperatively. Five patients underwent further surgery. One who is now dead had a high tibial osteotomy and another an arthrodesis 1½ years after meniscectomy from an already degenerate joint. One young man had a patellectomy for osteoarthrosis 4 years after excision of a lateral horizontal cleavage lesion. He still cycles to work at the coal mine, but he required excision of a stitch granuloma, as did one other patient. Recently, a middle-aged man had loose bodies removed from his knee 8 years after meniscectomy.

In summary, 46 per cent regarded themselves as 'cured' and 47 per cent as 'improved' usually 'greatly so'. Five per cent said they were 'the same' and 2 per cent 'worse'. In all but 2 of this group of unimproved patients osteoarthritis was already established but they enjoyed some transient benefit from meniscectomy. The remaining 2, however, were healthy young people, one with evidence of chondromalacia patella and the other with an apparently perfect knee and he played competitive club rugby two or three times a week. Sixty-seven per cent of those who had had night pain said that it was 'cured' and 25 per cent claimed that it was 'improved', while 8 per cent remained 'the same' or 'worse'.

Discussion

Whereas the surgical incidence of these lesions predominates in the middle-aged, this series included 3 teenagers and 5 patients over the age of 70.

The differences relating to sex and side between this clinical series and the reported autopsy subjects (Noble and Hamblen, 1975) for the same type of tear suggests that factors in addition to the possession of the lesion cause symptoms.

Occupation might be a factor to cause gross tearing with associated symptoms from an underlying and much commoner microscopic degenerative process. In Noble and Hamblen's (1975) study such changes were invariably found amongst both macroscopically torn and untorn menisci, and Pfeil (1966) and Zippel (1964) have reported similar findings. It may well be that there is an invariable and therefore 'normal' background of physiological ageing changes which predispose to microscopic tears from laminar shearing forces. If that is the case, then miners could be particularly vulnerable because of the flexion–rotation strains to which they are subject. In half the patients the onset was acute and traumatic, often occurring in coal miners, whose preponderance amongst the males in this series greatly exceeded their prevalence in this region.

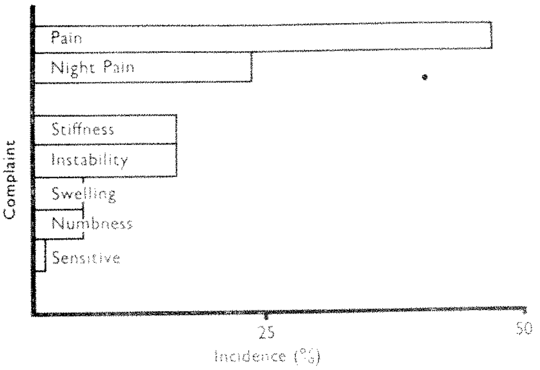

Fig. 6. Incidence of symptoms at follow-up.

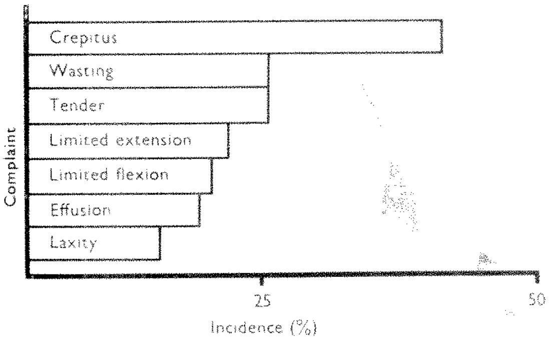

Fig. 7. Incidence of physical signs at follow-up.

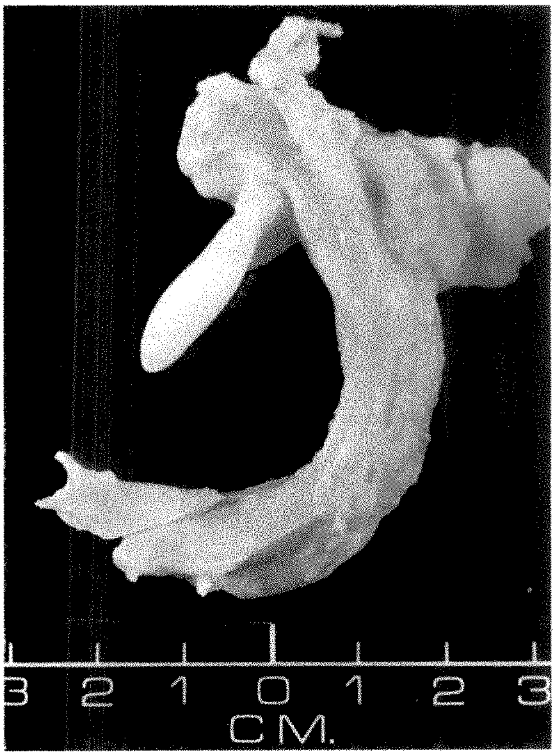

Fig. 8. Horizontal cleavage lesion with polypoid tag.

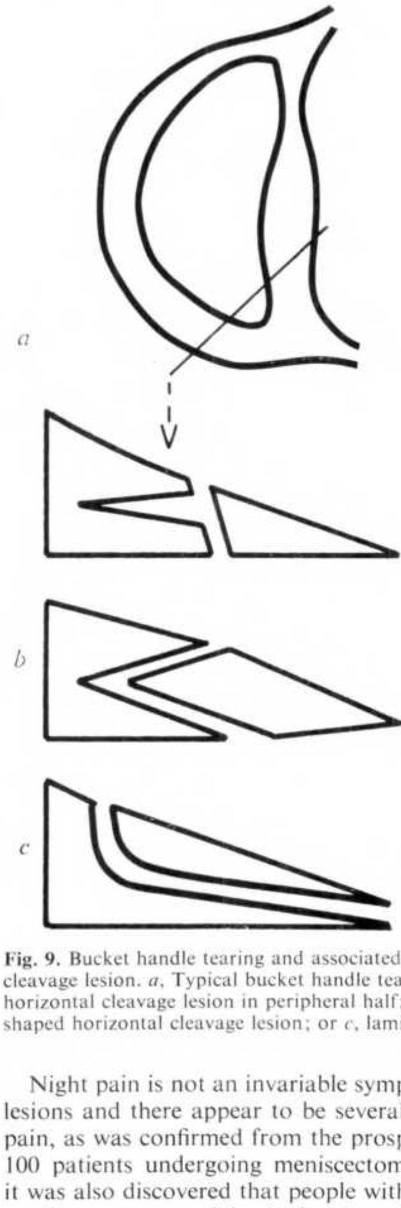

Fig. 9. Bucket handle tearing and associated horizontal cleavage lesion. *a*, Typical bucket handle tear with horizontal cleavage lesion in peripheral half; or *b*, diamond-shaped horizontal cleavage lesion; or *c*, laminar tear.

Night pain is not an invariable symptom with these lesions and there appear to be several types of night pain, as was confirmed from the prospective study of 100 patients undergoing meniscectomy, from which it was also discovered that people with other types of meniscus tear complained of night pain.

Mechanical symptoms and signs, such as locking and mechanical instability, might be explained by the existence of polypoid tags arising from the posterior third of a meniscus which may become trapped between the condyles (*Fig.* 8), or from associated bucket handle tearing, as represented diagrammatically in *Fig.* 9. This shows the several ways it can occur, one of which, the laminar displaced tear, is shown in *Fig.* 10. It may be of practical value to separate the group with only painful symptoms from those who also complained of locking and/or mechanical instability.

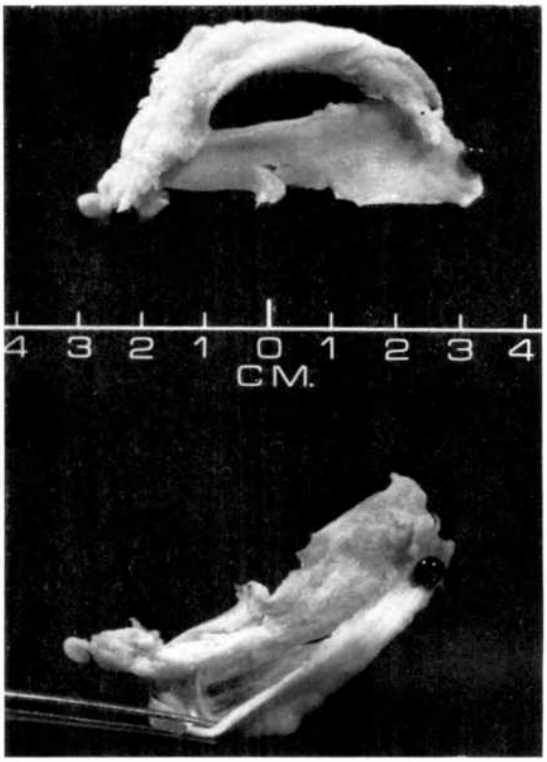

Fig. 10. Photograph of a bucket handle tear and associated laminar lesion.

In 1970 Le Quesne et al. reported 80 per cent lasting relief from juxtameniscal pain by means of cortisone injections in a small series of patients including those with degenerative menisci. Such simple therapy may be advisable in the first instance in all those whose complaints exclude mechanical symptoms. Miller et al. (1958) reported relief from knee pain in nearly two-thirds of a large series by various injections of which the placebo effect seemed to be important. Bentley and Goodfellow (1969), however, have warned of the dangers of intra-articular hydrocortisone injections.

Conclusions

1. The horizontal cleavage lesion probably exists much more commonly than symptoms arising from it. Therefore, other factors must be involved in the production of symptoms.

2. Although night pain is a cardinal symptom, it is not invariable. There are different types of night pain and their significance varies.

3. Although the results of meniscectomy were usually good, less than half the patients were completely relieved of pain and only two-thirds had their night pain completely abolished. Recovery may be slow, so that surgery is not to be undertaken lightly, and patients' response to surgery may be capricious.

4. Alternatively, there may be a group of middle-aged patients, hitherto labelled as 'osteoarthritic', with mechanical symptoms from a degenerate meniscus due to a polypoid tag or associated bucket handle tear who might benefit from a meniscectomy. Surgery should be primarily offered to this group.

5. Local anaesthetic with or without extra-articular cortisone injection may be worth trying in patients with predominantly painful symptoms.

Acknowledgements

Grateful thanks are due to all the consultant staff of Princess Margaret Rose Orthopaedic Hospital who have allowed their patients and material to be studied.

Special thanks are due to Professor J. I. P. James and Professor D. L. Hamblen who suggested and supervised the study.

Pressure measurements beneath below-knee amputation stump bandages: elastic bandaging, the Puddifoot dressing and a pneumatic bandaging technique compared

P. A. ISHERWOOD, J. C. ROBERTSON AND A. ROSSI*

SUMMARY

Elastic wrap bandaging is unreliable and dangerous in terms of pressure and pressure distribution (tourniquet effect). The Puddifoot dressing is safe and is less likely to produce a tourniquet effect. The range of pressures it produces is low—possibly too low to achieve ideal moulding or oedema control. A pneumatic bandage achieved a relatively narrow range of pressures between capillary and arteriolar blood pressures. It minimized tourniquet effects and differences between skilled and unskilled bandagers. It is sufficiently promising to merit development.

THE role of bandaging in amputation stump management is a controversial subject, and likely to remain so. A bandage may be required to act as a dressing that, despite movement, can stay on for hours, days or even weeks, to hold tissues in the control of stump oedema or to mould amputation stumps to facilitate prosthetic fitting. It should be cheap, disposable, easily sterilized and permit easy access and observation. Above all it must be safe even when applied by unskilled, ill-informed, geriatric and handicapped users to tissues which may be compromised by ischaemia, metabolic or neurological diseases or recent surgery. A stump bandage will exert pressure on the skin, yet it is not known how much pressure the skin and subcutaneous tissues can withstand and for how long. Pressures at isolated points beneath applied stump bandages do not appear to have previously been recorded in the literature.

The work of Müller et al. (1954) with erythema time gives some idea of how the pressure/time factors operate on non-weight-bearing skin in the absence of shearing strains. They maintained that sustained pressures in excess of 0·04 kg/cm^2 (25 mm Hg) are potentially harmful. Spiro et al. (1970), in a series of femoral vein blood flow measurements during varying degrees of lower limb compression, discovered that a sustained pressure of above 15 mm Hg decreased flow. Provided that bandage pressure does not exceed intravascular hydrostatic pressure, bandaging will limit the formation of oedema but will not increase the vascular resistance to the detriment of blood flow. Intracapillary pressure varies with posture (Chant, 1972), and in the recumbent position this is exceeded in the lower limb by externally applied pressures of 15–20 mm Hg. As intracapillary pressure varies with dependency, the ideal bandage should provide a graded pressure, which is maximum at the most dependent distal point, decreasing proximally. A hydrostatic bandage devised along these lines has been described elsewhere (Wood, 1968), but despite its advocates (Chant, 1972) is not in general use. Variations in lower limb venous flow, as assessed by radiological dye studies with varying degrees of externally applied pressure, were correlated with distal venous pressure measurements by Hosni et al. (1968), who found that pressures greater than 15–20 mm Hg applied to the popliteal fossa caused a tourniquet pressure effect even when the entire limb was wrapped. They recommended that bandages should stop below the knee joint. Johnson (1972) believed that no dressing with a pressure exceeding 10 mm Hg should be left on overnight. Redhead (1974), however, has applied cycled pressures never dropping below 25 mm Hg to postoperative limbs with benefit.

At present it is rare for a bandager to check clinically the pressures he applies, and an attempt has been made to ascertain the pressure distribution beneath three different types of bandages applied to a series of healed below-knee amputation stumps. Stump bandaging is employed routinely in the rehabilitation of the amputee to control stump oedema and facilitate moulding.

Patients and methods

A series of 21 below-knee amputation stumps of 17 unselected patients of both sexes with vascular, diabetic or neurological disease were studied. All the stumps were considered to be surgically healed but varying in maturity. The patients were studied in the semirecumbent position lying on hospital beds or on a firm couch. The bandages compared were a full length (5 yd) 4-inch wide Rayolast elasticated roll, which is the wrap bandage routinely used in the Limb Fitting Centre of Queen Mary's Hospital, Roehampton, the Puddifoot stump bandage (Puddifoot et al., 1973) and a pneumatic bandage designed by one of us (P. A. I.). The Rayolast bandage was applied as shown in *Fig.* 1 at half-stretch, more firmly at the end of the stump and less at the top. The knee joint was not included

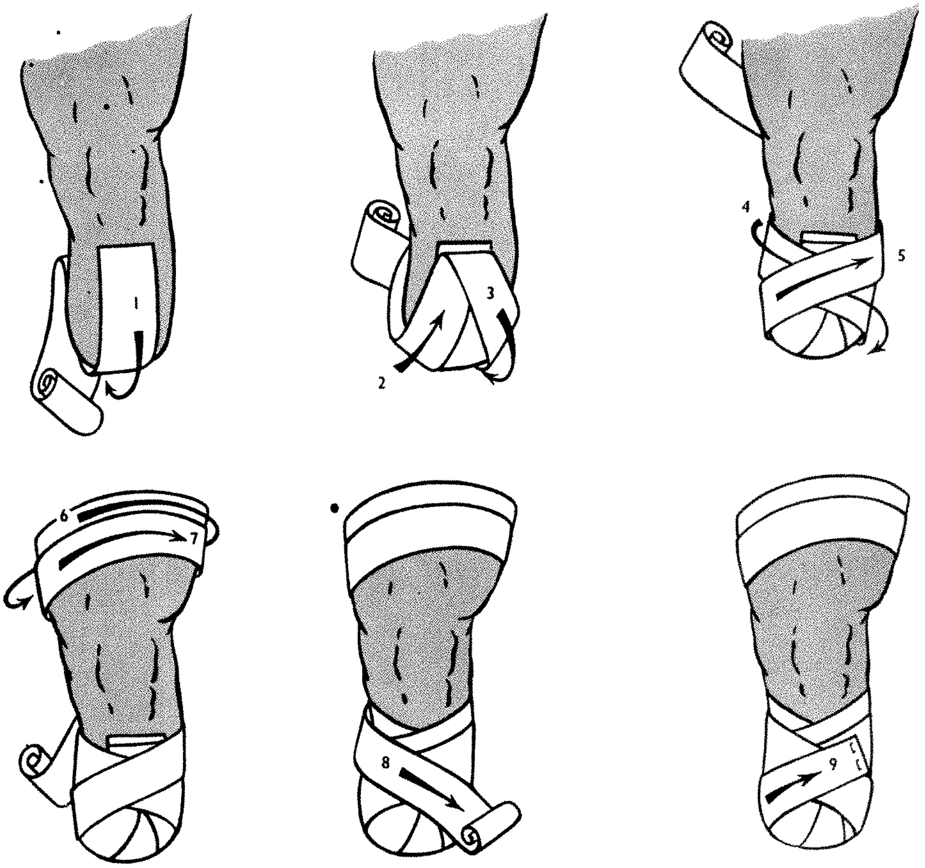

Fig. 1. The important turns of a below-knee stump bandage. Diagonal turns are repeated as often as necessary to cover the stump adequately.

anteriorly to facilitate joint movement, and the wrap was held in place by several loose turns around the thigh just above the patella. This is the approved method of applying this bandage at the Limb Fitting Centre. The Puddifoot dressing and method of application are described elsewhere (Puddifoot et al., 1973). The pneumatic bandage consists of four welded transparent PVC bags of 24 × 6 cm, partially filled with air and sealed. Each bag was wrapped lengthways with its middle portion over the end of the stump, lying side by side along the stump and crossing over each other distally. They were held in place by a Rayolast bandage which was simply wrapped in a circular fashion at about half-stretch around the bags, no particular attempt being made to cover the end of the stump, and held in place by a couple of turns above the knee. The knee joint was not covered anteriorly. Before any bandages were applied six pressure sensors were attached to the stump in the following positions: anterior tibial tubercle, head of the fibula, medial side of the knee at a point opposite the head of the fibula and the centre of the popliteal fossa. The remaining two sensors were applied at the end of the stump, one directly over the end of tibia and the other over the adjacent posterior soft tissue. The apparatus is shown in *Fig*. 2. When the pressure in the system exceeds the forces compressing the flattened sensor, the plastic envelope balloons, so parting the contacts and switching off the light. The pressure is then reduced at a rate of 2 mm/sec until the light comes on again,

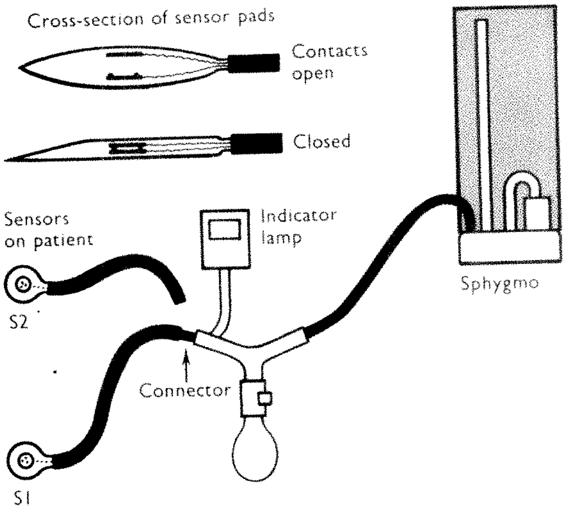

Fig. 2. The pneumatic/electric pressure sensor.

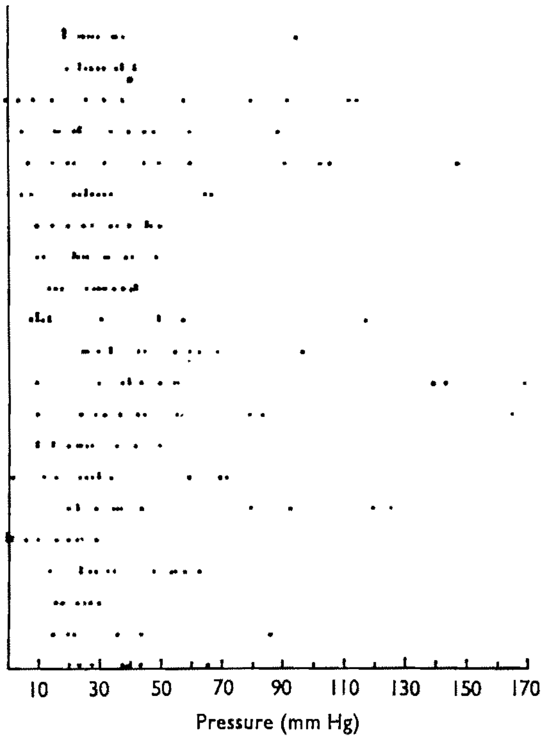

Fig. 3. Range of pressures recorded for Rayolast bandages. ○, Skilled bandager. ●, Unskilled bandager.

indicating the pressure between the surfaces. The apparatus was tested against known heights of water at a range of temperature varying from ambient to above body temperature (23–38 °C). The maximum deviations from the calculated values were +2·1 and −3·1 mm Hg. It was found that readings below 11 mm Hg were unreliable. Bandages were applied by staff skilled in bandage application including physiotherapists, nursing staff trained in the care of amputees and two of the authors (J. C. R. and A. R.). Pressures beneath the bandages after skilled application were compared with those of unskilled bandagers, i.e. the amputees themselves, occasionally assisted by their relatives. Measurements were taken immediately after bandage application over a 5-minute period. Twenty-two series of pressure recordings were measured with the stump resting on the bed and nine series with the stump elevated, the patient supporting the thigh.

Results

Pressure readings from each site were measured with an adapted sphygmomanometer machine. Above 11 mm Hg the apparatus was accurate to within 3 mm Hg, but although readings below this level were considered individually unreliable they were included in the statistical treatment of results. *Figs.* 3–5 show the range of pressures recorded for each of the three bandages, illustrating the pressures developed at each sensor site for each of the 21 stump applications by both skilled and unskilled bandagers with the stump

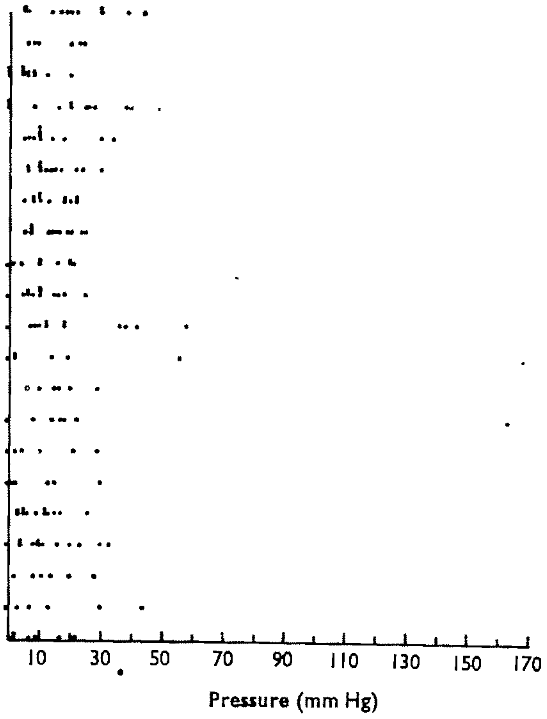

Fig. 4. Range of pressures recorded for Puddifoot bandages.

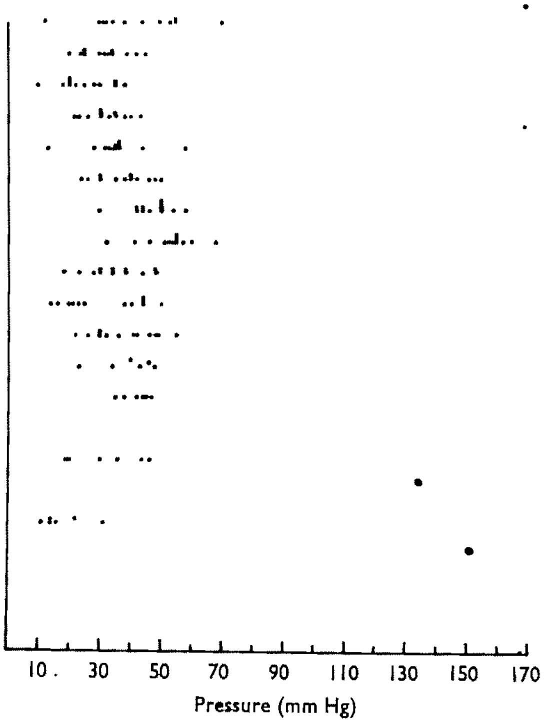

Fig. 5. Range of pressures recorded for pneumatic bandages.

resting on a bed or couch. The means of the pressures recorded from each individual sensor site were calculated for the three types of bandage. The calculations were made for the series of 21 skilled and unskilled applications with the stump resting, and similarly for the 9 skilled applications with the stump elevated. These results were recorded to assess and compare the presence of any tourniquet effect (*Table I*). In a second series of 22 Rayolast applications to 7 below-knee amputation stumps of 5 patients, two additional sensors were positioned proximally on either side of the tibial tubercle to assess more fully the distribution of proximal ring pressure. Readings were taken immediately after bandage application by a random selection of skilled and unskilled bandagers and the means of the pressure recordings from each site were calculated (*Table II*).

Discussion

As can be seen from *Figs*. 3–5 the greatest range of pressures is beneath the Rayolast, and the majority of the highest readings in this group follow unskilled applications. This is not surprising as variations in stump diameter at different levels may result in a variable number of turns of the bandage to be applied, and so portions of the stump may have more bandage coverings than others. Considerable practice is needed to judge bandage tension during application and few bandagers follow Fegan's (1973) advice to feel the tension in the bandaged tissues. Chavatzas and Jamieson (1974), in measurements of skin blood pressure, recorded levels of 59–73 mm Hg for healthy pretibial skin and levels of 17–50 mm Hg for pretibial skin of patients with popliteal stenosis. Two in 13 of the pressures recorded beneath Rayolast bandages at similar sites were in excess of 59 mm Hg. This bandage was comfortable, but although easily applied by the patients themselves, was not always applied in the approved manner despite repeated instruction. The Puddifoot dressing has a much narrower pressure scatter distribution and pressures were generally much lower than those under the Rayolast. Almost half of the readings, however, were below 11 mm Hg, and 1 in 11 was zero. As a supportive dressing it was comfortable when on, although it tended to be painful during the process of application in the early post-operative period, but with practice was easily applied by most patients. Clinically, it has been shown to aid moulding and oedema control (Puddifoot et al., 1973), despite the low pressure readings obtained. The pneumatic bandage also shows less pressure scatter than the Rayolast, and while 1 in 18 of the pretibial pressure measurements was 60 mm Hg, only 1 was less than 11 mm Hg. This was a predicted result as the pressure applied to the bags by the Rayolast at the sides of the stump is fairly evenly transmitted throughout the bag to the end of the stump. The bandage was comfortable, with a little practice easily applied by the amputee and did not tend to slip.

A tourniquet effect was considered to have been produced when the mean of the lowest proximal sensor pressure readings was greater than that of either of the distal sensors. Using this criterion the maximal tourniquet effect was seen with the stump resting after unskilled application of Rayolast (*Table I*). A tourniquet effect was still recorded following skilled application, although this was less and disappeared following elevation of the stump. This might be anticipated from the reduction in pressure on the popliteal fossa following elevation. No tourniquet effect was demonstrated with the Puddifoot dressing and there appears to be an appreciable difference between the higher distal end and the lower proximal pressures. Apart from a minimal tourniquet effect following elevation, there was no such effect with resting measurements following application of the pneumatic bandage. This range is probably more effective than that of the Puddifoot dressing for oedema control, but is uncomfortably close to skin arteriolar blood pressure in arteriopaths.

From the second series of 22 Rayolast applications with the sensors dispersed proximally, the highest mean was calculated from recordings at the tibial tubercle, as might be expected (*Table II*). An interesting finding is the low mean pressure calculated at the medial, anteromedial and anterolateral sites relative to the popliteal fossa with the stump resting. This may be due, at the medial site, to the relatively soft subcutaneous tissue, and for the latter two sites, to a

Table I: CALCULATED MEAN PRESSURES AT EACH SENSOR SITE FOR EACH TYPE OF BANDAGE

bridging effect, the sensors being in a hollow part of the proximal circumference. Possibly these sites provide exits for lymphatic drainage as important as the popliteal region in the below-knee amputee.

In conclusion, we feel that Rayolast bandaging is potentially dangerous, especially if applied by the unskilled, that the Puddifoot dressing exerts too low a pressure to the stump for ideal moulding and that the pneumatic bandaging technique produces a higher, more evenly distributed therapeutic range of pressures, is safe and worthy of further clinical trial.

Acknowledgements

We wish to thank Dr I. H. M. Curwen, Mr K. P. Robinson, Mr A. G. Rutter, Dr M. Vitali and the surgeons of the Limb Fitting Centre, Roehampton, for their kindness in allowing us to approach their patients. Without the help of Miss B. Davies and Miss C. Van der Ven and the support of the nursing staff of Queen Mary's Hospital this study would not have been completed.

Reviews and notices of books

The Arteries and Veins of the Human Spinal Cord from Birth

G. F. Dommisse, Pretoria. 245 × 185 mm. Pp. 104+vii. Illustrated. 1974. Edinburgh: Churchill Livingstone. £9.

THE classic anatomical descriptions of the vascular anatomy of the spinal cord, commencing with Adamkiewicz in 1881 and followed by many similar studies, would seem to have left little for the anatomist to add. However, G. F. Dommisse finds points to criticize in these previous studies and many discrepancies which have been the stimulus for him to embark on his own dissections.

This is a very thorough study carried out on forty-two cadavers including thirty neonates utilizing a technique of pressure injection of latex complemented in some cases by radiographic analysis employing Micropaque in gelatin. Dissection of arteries and veins from their origin to their termination with the cord *in situ* was carried out with a microscope and with photographic reproduction. Measurement of the diameter of the anterior and twin posterior longitudinal arterial channels and their feeder vessels was made and recorded at all levels and the findings in the neonates were compared with those in the adult. Thirty colour plates illuminate these dissections very vividly.

The author puts forward the view that in order to provide an adequate and equalized perfusion pressure in the small vessels penetrating the spinal cord there is an elaborate system of anastomostic channels arranged in three situations: on the cord itself, consisting of arcades between the main longitudinal trunks, around the theca extradurally, forming links between the segmental arterial vessels, and thirdly in the extravertebral tissue planes.

This study confirms many of the already well-known anatomical features, in particular the vulnerability of the thoracic segment of the cord deriving from the narrowness of its anterior spinal vessel and the paucity and fine calibre of its feeder arteries. On the other hand, the author points out the great variations in the normal vascular supply and emphasizes that the artery of Adamkiewicz may arise at any level from the fourth dorsal to the second lumbar and that purely on its anatomical situation no feeder vessel to the spinal cord can be disregarded.

The book fills in some gaps in knowledge of the vascular anatomy of the cord and will take its place with other detailed studies of the past. It will be of interest to the anatomist, the pathologist and to the surgeon operating in this hazardous field.

VALENTINE LOGUE

China Medicine as we saw it

Edited Joseph R. Quinn. 230 × 150 mm. Pp. 430+xii. 1974. Bethesda, Md: US Department of Health, Education and Welfare. No price given.

THIS is a delightfully readable book on Chinese medicine in 1974. The authors cover many topics such as general medicine, surgery, public health and nursing. It is, of course, impossible in such a short book to go into great depth on each subject, but there is sufficient detail to give an accurate insight into China's many medical problems, as well as many of her medical successes.

There are four chapters on traditional Chinese medical practice and mixed traditional and Western practice, which describe herbal remedies, acupuncture and acupuncture anaesthesia and reattachment of limbs, as practised in Shanghai. In the public health section the training and work of the 'barefoot doctor' are described. There is an excellent chapter on applied microbiology by a microbiologist who was born in China and who was able to communicate expertly with the Chinese.

This book contains something for everyone who is interested in Chinese medical practice, or indeed in medical practice in countries outside the United Kingdom. There are, unfortunately, political references and ideas in this book, but the influence of politics on medicine in China makes this imperative.

This should be regarded as a book for bedtime reading, rather than an authoritative textbook.

IAN CAPPERAULD

Atlas of the Battered Child Syndrome

J. M. Cameron and L. J. Rae, London. 245 × 185 mm. Pp. 90+ix. Illustrated. 1975. Edinburgh: Churchill Livingstone. £8·50.

THIS short book has been compiled by a forensic pathologist and a radiologist with a contribution from an ophthalmologist, Dr Alan Mushin. At atlas should be judged on its comprehensiveness and the pertinence, clarity and accuracy of its illustrations. These criteria are met successfully in the radiological chapter but other aspects are neither as well covered nor portrayed. The atlas will be of interest to all who are involved with abused children but is primarily intended for doctors who are responsible for the clinical recognition of the syndrome. The differential diagnosis of the radiographic appearances is fully considered and well illustrated, although some mention might have been made of the comparative rarity of congenital syphilis and infantile scurvy. It is surprising that the differential diagnosis of bruises is not discussed because the exclusion of natural causes of bleeding is of considerable clinical and legal importance.

Criticism of the brief, superficial account of the general features of the battered child syndrome and its management is perhaps misplaced. Nevertheless it is unfortunate that speculative figures regarding prevalence and mortality are reiterated, and unconfirmed statistics about recurrence rates are quoted. Children's departments disappeared with the establishment of 'generic' social service departments, while the authors omit the recommended and now largely followed procedures set out by area review committees which place upon the case conference the major role in deciding management.

The book is well produced and the illustrations are of excellent quality. It should find a place on the shelves of every X-ray department but will not be as useful to those dealing with wider aspects of the problem. At £8·50 it seems a somewhat costly production.

THOMAS E. OPPE

Biochemical Values in Clinical Medicine

Robert Duncan Eastham, Newcastle upon Tyne. Fifth edition. 175 × 100 mm. Pp. 237. 1975. Bristol: John Wright. £2.

THIS is the fifth edition of an old favourite, and it is a measure of the success of this book that it has gone through five editions, three reprintings and several foreign editions since it first appeared in 1960. Basically, it is a description of normal ranges for biochemical values in clinical medicine with notes on conditions that affect the performance and the evaluation of the tests and references to the relevant literature. The items are arranged in alphabetical order with the origins of the test material, but are cross-indexed by means of a comprehensive index of subjects at the back of the book. The value of the whole compilation is enhanced by presenting it with a firm cover in a size that fits comfortably into the pocket of a white coat. House surgeons must find it invaluable in the day-to-day care of their patients, but it is also a most convenient, and as far as I can judge accurate, source of information for more senior clinicians as well. This book is excellent value for money.

MICHAEL HOBSLEY

The Etiology of Human Breast Cancer

A. N. Papaioannou, Athens. 240×165 mm. Pp. 228, with 2 illustrations. 1974. Berlin: Springer-Verlag. DM.56.

This is an excellent book and its arrival on the oncology scene is timely. The past few years have produced a wealth of information and speculation concerning the aetiology of human mammary cancer. In this book the author meticulously sifts and analyses all the available evidence and presents his conclusions to the reader in a clear and concise manner.

The author looks first at endocrine considerations and in some ways this is the most provocative part of the story. To quote the author: 'Endocrine factors play an unquestionable, clearcut and fundamental role in experimental breast carcinogenesis.' The evidence in humans is less convincing, but nevertheless many of the factors which undoubtedly influence the relative risk of developing the disease have an endocrine basis. The author makes a very reasoned evaluation of these factors and gives due prominence to the excellent international epidemiological studies of MacMahon and his colleagues.

Chapters 2 and 3 deal with genetic and viral considerations respectively. The former is full of interesting detail, much of it anecdotal. The latter has a more scientific flavour and provides a thoughtful account of a subject which has interested research workers for many decades.

In the fourth and last major chapter of the book the author devotes disproportionate space to immunological considerations, and this is perhaps understandable in view of his own special interests, but the welcome objectivity of the previous chapters is lost as a result. The list of references at the end of this particular chapter is formidable and many are irrelevant to the main theme of the book.

The concluding section deals with a number of miscellaneous factors which may be involved in the aetiology of breast cancer. Of particular interest is a short but intriguing examination of the role of 'psychological stress' in carcinogenesis.

This book is a welcome addition to the already vast literature on mammary cancer and is unreservedly recommended to all who have an interest in the subject.

IAN BURN

Radiology of Bone Diseases

George B. Greenfield, Chicago. Second edition. 210×280 mm. Pp. 667+xvi. Illustrated. 1975. Oxford: Blackwell Scientific Publications. £27·50.

In the second edition of this most valuable and useful book on the differential diagnosis of bone disease, Dr Greenfield has greatly expanded the text, brought the topic up to date and added a new chapter on arthritides. The author has adhered to the concept of presenting his material according to radiological features of the various conditions, clearly describing each entity in some detail, profusely illustrating it and adding helpful basic clinical, biochemical and pathological information.

The main sections of the book include a general description of an analytical approach to bone radiology, and loss of bone density, including osteoporosis, osteomalacia, hyperparathyroidism and other entities. There is a comprehensive chapter on alterations of bone texture, an extensive description of lesions affecting the epiphyseal region and an equally comprehensive section on changes in size and shape of bone. There is a very helpful chapter on the cardinal radiographic features which deals very fully with the main diagnostic appearances of specific conditions. Bone tumours are dealt with in a section on solitary lesions. There is a useful chapter on soft tissue appearances and finally a very comprehensive section on joint disease.

The part of the book dealing with metabolic bone diseases has been completely rewritten and a great deal of new information has been presented on bone changes in renal disease. There is a fully illustrated description of the various types of bone dysplasia, which are well annotated and tabulated.

As in the first edition, the large number of illustrations are of high quality, well chosen and used as a key to interpretation with clear, descriptive captions. Each chapter carries its own bibliography, which is very extensive, bringing the radiological literature well up to date.

The book is eminently readable, a mine of information, and although expensive it is nevertheless a valuable addition to one's library. It will certainly be of great help to orthopaedic surgeons, radiologists and all who are interested in bone disease. Dr Greenfield has done a great service to the speciality of radiology in producing this monumental text which can be highly recommended in every respect.

R. E. STEINER

Advances in Surgery, Volume 8

Edited R. M. Zollinger, Columbus, Ohio. 230×155 mm. Pp. 333+xiv. Illustrated. 1974. London: Lloyd-Luke. £13·50.

This volume deals with a number of important topics where significant change has taken place in surgical practice. It would be difficult to criticize the scholarly review on the surgical treatment of duodenal ulcer by Professor Goligher or the section on hepatic resection by William P. Longmire. The sections on biliary atresia, the surgical approach to nutritional problems and the management of malignant melanoma are perhaps more controversial, but nevertheless provide a great deal of useful information and much food for thought.

There are two excellent sections, one on the effect of halogen anaesthetics on liver metabolism and the immune response and the other on the contributions of immuno-assay to surgery, both of which provide full information on two rather complex changes which affect the management of surgical patients.

The final sections on problems in the intensive care unit and the treatment of wound failure would be of interest to all surgeons.

This book continues to maintain the reputation of its predecessors in providing the surgeon with up-to-date information on topics of general interest.

C. G. CLARK

Clinical Embryology for Medical Students

Richard S. Snell, Washington. Second edition. 185×255 mm. Pp. 481. Illustrated. 1975. Boston: Little, Brown and Co. $12.50 paper, $17.50 cloth.

The first edition of this book in 1972 drew attention to the value of embryology during the student's clinical studies, particularly in relation to congenital abnormalities. The text and its accompanying line drawings provided the essentials of developmental anatomy in an attractive, agreeable way and appealed to the student. The extra 120 pages in the second edition are accounted for by the inclusion of many excellent photographs of congenital abnormalities and by the introduction of a series of clinical problems or exercises at the end of each chapter. In attempting these, the student is expected to test his knowledge of embryology in the clinical context and thereby appreciate its relevance. To derive the full benefit of the scheme, however, it will be necessary to mix embryology with clinical study (or vice versa) in far greater measure than most curricula allow at present.

JOHN MCKENZIE

Stress Fractures

Michael Devas, London. 195×250 mm. Pp. 240+viii. Illustrated. 1975. Edinburgh: Churchill Livingstone. £15.

This monograph represents a very personal and unique experience of several hundred stress fractures and avulsions which the author has described from 'purely' clinical and radiographic standpoints. It began over 15 years ago when the Stress Fracture Bureau at the Middlesex Hospital was set up. There are examples from almost every long and short mature bone of the human skeleton, and all are well illustrated and discussed. Even the horse and the greyhound are shown to have their problems of a similar nature. Biopsy material is naturally very limited and this makes it difficult to add to present day knowledge about the aetiology or indeed aetiologies of these conditions. Under the heading of 'Epilogue' Mr Devas considers very carefully the effects of muscle contraction, and osteoporosis, and their interaction. He also emphasizes that a great deal of experimental work has yet to be done to demonstrate why cellular and hence structural failure has occurred.

The literature has been thoughtfully reviewed and such a grouping for this relatively rare pathology is most helpful.

R. B. DUTHIE

Pediatric Orthopedic Nursing

Nancy E. Hilt and E. William Schmitt, Atlanta, Georgia. 254 × 175 mm. Pp. 248 + xviii, with 301 illustrations. 1975. London: Henry Kimpton. £6·15.

THIS is a really splendid book. The entire field of nursing care of the orthopaedic child is covered in a practical manner without neglecting the emotional problems which are encountered when a child undergoes prolonged surgical attention. The text is highly informative and the illustrations are clear and concise. It may be read with pleasure from cover to cover or can be used as a reference book. It will be found invaluable for teaching nurses. So often textbooks for nursing and paramedical staff have a patronizing tone, but these authors show that it is possible to be simple and instructive without being condescending. This book will, in my opinion, become the standard reference book on paediatric orthopaedic nursing in the foreseeable future. It cannot be commended too highly.

LIPMANN KESSEL

Abdominal Operations. Volumes 1 and 2

Edited R. Maingot. Sixth edition. 250 × 180 mm. Vol. 1: pp. 1220 + xxix; Vol. 2: pp. 2264 + xxiii. Illustrated. 1975. Hemel Hempstead, Herts: Prentice-Hall International. £46·75.

THE sixth edition of this famous work is a worthy successor to previous editions and Rodney Maingot is to be congratulated on drawing contributions from so many distinguished authorities. Descriptions of most of the operations performed by alimentary surgeons are interlaced with discussions of basic principles, sections on physiological and pathological aspects, methods of investigation, historical notes, etc. As a comprehensive text, sensibly presented in two volumes, it is well worth having if your work is mainly in the abdomen and you have not already acquired publications that cover essentially the same field. However, it is atrociously expensive even by present day standards and I doubt if the surgical registrar or Fellowship candidate should—or could—buy it; he would undoubtedly be glad to find it in his hospital library as a superb source of reference on practical and theoretical matters.

Having thus recommended it, I cannot refrain from some criticisms which might be considered for a further edition in a few years. Monographs are all the rage, but I think there will continue to be a place for major 'spectaculars' such as this.

Some subjects must be included and others expanded. For example, proximal gastric vagotomy receives scant attention; the trans-sphincteric approach to the rectum deserves a full description; prolapse of the rectum merits a more thorough exposition; as fissure-in-ano is dealt with, there seems no reason to exclude haemorrhoids; prevention of deep vein thrombosis is worthy of more than three lines.

As a text largely devoted to technique, the avoidance of excessively dogmatic statements is remarkable, and the policy that led to this must be sustained vigorously.

Now to relative trivialities. References are dealt with in different ways in different chapters which is wrong. There seems to be a schizophrenia about whether to use the English or American spelling of such words as haematemesis, colour and anaesthetized, and the common bile duct becomes the choledochus occasionally. To convert inches to centimetres seems reasonable, but it is surely impossibly precise to describe an incision as 7·62 cm from the pyloric sphincter—why not go metric throughout anyway? Some of the illustrations are poor because of excessive shading or detail, and one is frankly silly—we do not need a line drawing to show a surgeon with a hand in an abdomen doing a laparotomy! It also seems out of place to go into such detail as when a patient may get up 'for bedmaking'—particularly when the advice is out-of-date. Despite these blemishes, it is an excellent book—if you can afford it.

ALAN G. COX

Digestive Surgery. Proceedings of the Second World Congress of Collegium Internationale Chirurgiae Digestivae

Edited L. F. Hollender and G. D'Onofrio. 240 × 170 mm. Pp. 969 + xxxii. Illustrated. 1974. Padua: Piccin Medical Books. $60.

THIS long book of approximately one thousand pages comprises the Proceedings of the Second World Congress of Collegium Internationale Chirurgiae Digestivae, held in Strasbourg in June 1972. The volume is divided into sections on the physiology and surgery of the oesophagus and hiatal hernia, the stomach and duodenum, the small intestine, the colon, the rectum and anus, the bile ducts, the pancreas, portal hypertension, etc. As might be expected, some of the contributions are now rather 'old hat', but it is useful to have so many valuable papers collected into one volume. The quality of the contributions is inevitably rather uneven but the general standard is high. It is perhaps invidious to pick out any particular papers for special mention, but there is the expected rash of communications on selective proximal/highly selective/parietal cell vagotomy and an interesting account by G. Holle et al. on the changes in the parietal cell mass after selective proximal vagotomy for gastric ulcer. Kronberger contributes a vigorous defence of gastric resection for chronic peptic ulcer, sentiments which echo those of McKeown in this country and Ochsner from the United States. De Miguel has an interesting paper showing how diarrhoea diminishes as the types of vagotomy become more refined. Brückner and his colleagues from Munich report interesting work on the effect of sympathectomy on pepsin secretion in cats with gastric fistulation. The fascinating data on Crohn's disease from Birmingham presented by J. Alexander-Williams et al. will by now be familiar to most British surgeons. There are fine accounts of the treatment of chronic pancreatitis and of portal hypertension from experts in these fields. Altogether, this is a stimulating publication which should be present in medical libraries, but which one would hesitate to recommend for purchase by the individual surgeon.

DAVID JOHNSTON

Lessons of Leucotomy

Edited Ashley Robin and Duncan Macdonald. 215 × 137 mm. Pp. 100, with 7 illustrations. 1975. London: Henry Kimpton. £2·25.

THE senior editor of this book is noteworthy in that he is one of the few psychiatrists who has paid attention to the need for an adequate control population with which to compare the results of prefrontal leucotomy. He himself, in his study from Runwell Hospital, found that his group of patients derived little benefit. The editors have had an almost impossible task in comparing the results on patients with different diagnoses undergoing different kinds of operation, and there is much evidence, though little of it as yet published, which shows that lesions are by no means always placed in the intended areas. The book contains a considered discussion of the methodology involved in a proper controlled trial and ends with a plea for some adequately controlled trials. It is to be hoped that such trials will indeed be carried out, for the occasional dramatic improvement seems far more than can be due to chance. For examples of this kind of improvement and for the various ill effects that may follow operation there is still no better study and certainly no more entertaining one than Partridge's *Prefrontal Leucotomy* (1950, Oxford, Blackwell). The present volume will encourage a more critical attitude in the future by those concerned with this operation. Neurosurgeons have with stereotaxis increased the accuracy of the lesions that they can produce; it is now the psychiatrists who must play their part.

The management of peptic oesophageal stricture	R. C. N. Williamson	448
The effect of raising the concentration of potassium in the blood or intestinal lumen on the transport of potassium in the dog intestine	Anne Hardy Smith and R. Shields	455
Environmental tests of linear flow ventilation for an operating theatre	The late Charles C. Scott and Thomas D. Guthrie	462
Bilateral idiopathic parotid duct strictures	M. Adiseshiah	468
General anaesthesia during early pregnancy	Leo Strunin, K. Knights, J. M. Strunin and Michael E. Ward	471
Renal transplantation in the unimmunosuppressed pig: an abnormal response	John Terblanche, Rosemary Hickman and C. J. Uys	474
Injuries caused by rubber bullets: a report on 90 patients	R. Millar, W. H. Rutherford, S. Johnston and V. J. Malhotra	480
Incidental appendicectomy with laparotomy for trauma	Lawrence W. Norton, Marna Sweeney and Ben Eiseman	487
A prospective study of acute pancreatitis	C. W. Imrie and A. S. Whyte	490
The use of the vas deferens in inguinal herniorrhaphy	Patrick Sames	495
Nitrogen mustard as adjunctive chemotherapy for breast carcinoma	James R. Hines and John S. Williams	497
Reviews and notices of books		501

Review paper

Bile salts and gallstone disease	Colin MacKay	505

Original papers

Orthotopic liver transplantation: an experimental study on the prevention of infections with Gram-negative organisms	S. W. Schalm, D. T. Popescu, D. van der Waay, R. A. F. Krom, W. D. H. Hendriks, J. L. Terpstra and C. Jerusalem	513
Fatal *Clostridium welchii* septicaemia following acute cholecystitis	M. T. Clancy and S. O'Briain	518
The removal of retained gallstones from the common bile duct: experience with sodium cholate infusion and the Burhenne catheter	D. C. Britton, B. S. Gill, R. M. R. Taylor and Oliver James	520
Long term changes in total body water, total exchangeable sodium and total body potassium before and after ileostomy	G. L. Hill, J. C. Goligher, A. H. Smith and W. S. J. Mair	524
Results of surgery for Crohn's disease in the Glasgow region, 1961–70	S. Young, I. S. Smith, J. O'Connor, J. R. Bell and G. Gillespie	528
Significance of faecoliths in the diagnosis of acute appendicitis	B. Gill and R. E. Cudmore	535
The changing pattern of hospital admissions for diverticular disease of the colon	James Kyle and Alan I. Davidson	537
The nature of haemorrhoids	W. H. F. Thomson	542
Localization of parathyroid adenomas by computer-assisted parathyroid scanning	P. J. Ell, A. Todd-Pokropek and K. E. Britton	553
True recurrence of hyperparathyroidism: proposed criteria of recurrence	H. Muller	556
Recurrent pleural effusion in chronic relapsing pancreatitis	Rudra Rasaretnam, A. B. V. Perera and M. Kumarasinghe	560
Xanthogranulomatous pyelonephritis: a report of 2 cases	O. S. Morgan, G. D. Nicholson, P. S. Johnson and D. W. Atkinson	563

Contents

		Page
An incision for *en bloc* nephrectomy	G. F. Cassie	565
Undetected aorto-iliac insufficiency: a reason for early failure of saphenous vein bypass grafts for obstruction of the superficial femoral artery	D. Charlesworth, P. L. Harris, F. D. Cave and Linda Taylor	567
Ossification in extradural fat in Paget's disease of the spine	Patrick R. R. Clarke and H. I. Williams	571
Nodular fasciitis: an unusual cause of extradural spinal cord compression	R. P. Sengupta, S. C. So and R. H. Perry	57
Peritoneal mesothelioma	P. S. F. Chan, T. W. Balfour, J. B. Bourke and P. G. Smith	57
The negative cholecystogram in gallbladder disease	D. R. K. Reid and I. M. Rogers	58
Reviews and notices of books		584

Number 8

Original papers

Observations on peripheral and central temperatures with particular reference to the occurrence of vasoconstriction	Lord Brock, J. M. Skinner and J. T. Manders	58
Aorto-iliac reconstruction with special reference to the extraperitoneal approach	Raymond Helbsy and A. R. Moossa	59
Oesophagogastrostomy without a drainage procedure in oesophageal carcinoma	I. B. Angorn	60
Antrectomy with Roux-en-Y anastomosis in the treatment of peptic oesophagitis with stricture	C. M. S. Royston, B. L. Dowling and J. Spencer	60
Gastric mucosal resection in the treatment of peptic ulcer: a 1–10 year clinical follow-up	R. M. Kirk	60
Abdominal tuberculosis: demonstration of tubercle bacilli in tissues and experimental production of hyperplastic enteric lesions	Pritam Das and H. S. Shukla	61
Primary gastric tuberculosis: a case report	R. E. Page, R. E. Williams and E. A. Benson	61
Congenital hepatic fibrosis: aspects of diagnosis and surgical management	G. S. Sokhi, J. J. Morrice, J. O'D. McGee and L. H. Blumgart	62
Splenic-gonadal fusion	A. K. Pendse, P. N. Mathur, M. M. Sharma and O. P. Gupta	62
Abdominoscrotal hydrocele	B. R. Parekh, G. Reinboth and O. P. Mishra	62
Triorchidism with normal spermatogenesis: an unusual cause for failure of vasectomy	M. Hakami and S. H. Mosavy	63
Immediate operative fitting of upper limb prosthesis at the time of amputation	K. P. Robinson, B. G. Andrews and M. Vitali	63
The bacteraemia associated with burns surgery	C. H. Beard, C. D. Ribeiro and D. M. Jones	63
A rabbit model of perforated appendicitis with peritonitis	D. W. King, J. F. Gurry, R. B. Ellis-Pegler and B. N. Brooke	64
The effect of noxytiolin in experimental peritonitis	D. W. King, J. F. Gurry and B. N. Brooke	64
Results of modified Robert Jones operation for clawed hallux	E. I. M'Bamali	64
Lymphosarcoma of the breast	Charles F. Ross and Arnold Eley	65
Surgical Research Society		65
Obituary: Vincent Zachary Cope		66
Reviews and notices of books		67

Number 9

Original papers

		Page
Whither thyrotoxicosis?	W. Michie	673
Surgical treatment of thyrotoxicosis: results of 272 operations with special reference to preoperative treatment with anti-thyroid drugs and L-thyroxine	Peter Heimann and Jan Martinson	683
Carcinoma arising in thyroglossal duct remnant: case reports and review of the literature	Prakash C. Saharia	689
Secondary carcinoma of the thyroid gland	John A. Thomson, J. S. Kennedy, M. K. Browne and J. Hutchison	692
The significance of occult skeletal metastases, detected by skeletal scintigraphy, in patients with otherwise apparently 'early' mammary carcinoma	C. S. B. Galasko	694
Acute cholecystitis	P. A. M. Raine and A. A. Gunn	697
Prognosis after portocaval anastomosis: a 15-year follow-up	R. Windle and J. H. Peacock	701
The effect of acute ethanol administration on the exocrine pancreatic secretion of the pig	I. C. Wheatley, G. O. Barbezat, Rosemary Hickman and J. Terblanche	707
The effect of heparin and of acid-citrate-dextrose solution on screen filtration pressure of blood in experimental hypotension	B. J. Pardy and H. A. F. Dudley	713
Acute segmental ischaemic enteritis in Thailand	Theodore P. Welch and Somsak Sumitswan	716
Cause and management of high volume output salt-depleting ileostomy	G. L. Hill, W. S. J. Mair and J. C. Goligher	720
Factors influencing local recurrence after abdominoperineal resection for cancer of the rectum and rectosigmoid	A. R. Moossa, P. C. Ree, J. E. Marks, B. Levin, C. E. Platz and D. B. Skinner	727
The transdiaphragmatic approach to the heart	E. W. J. Cameron	731
False abdominal aortic and iliac aneurysms	Demetrios Chavatzas and Crawford Jamieson	734
Gastric acid secretion following renal transplantation	J. S. F. Canavan, J. D. Briggs and P. R. F. Bell	737
Collagen biosynthesis in normal and hypertrophic scars and keloid as a function of the duration of the scar	R. D. Peter Craig, J. David Schofield and David S. Jackson	741
A technique for re-exploration of the saphenofemoral junction for recurrent varicose veins	Arthur K. C. Li	745
Parathyroid identification by methylene blue infusion	Donald L. Gordon, Mohan C. Airan, William Thomas and Leon H. Seidman	747
Selective surgery for abdominal stab wounds	A. Thavendran, A. Vijayaragavan and Rudra Rasaretnam	750
Reviews and notices of books		753

Number 10

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

Barber's Company Symposium on Malignant Disease of the Thyroid Gland

		Page
The pathology of thyroid malignancy	E. D. Williams	757
The aetiology and diagnosis of malignant tumours of the thyroid gland	J. S. H. Wade	760
The surgery of thyroid cancer	Ivan D. A. Johnston	765
The non-surgical treatment of thyroid cancer	K. E. Halnan	769

Symposium on Gram-negative Septicaemia

Introduction	Miles Irving	772
Gram-negative septicaemia in surgical practice	Adrian Litton	773
Septic shock	I. McA. Ledingham	777

Short papers for the Moynihan Prize and Medal

The value of the radio-isotope hepatogram in the jaundiced patient	A. Watson, D. E. Bone, H. J. Testa and Bruce Torrance	781
Observations of gastric mucosal blood flow using ^{99}Tc^{m} in rat and man	T. V. Taylor, B. R. Pullan, J. B. Elder and Bruce Torrance	788
Prophylactic interparietal povidone-iodine in abdominal surgery	O. J. A. Gilmore and P. J. Sanderson	792
Use of logic-based flow patterns in the investigation and management of surgical disorders	B. W. Ellis	800
Feasibility of screening for breast cancer	W. D. George	804
Sex hormones in breast disease	P. C. England, L. G. Skinner, K. M. Cottrell and R. A. Sellwood	806
Prediction of kidney viability before transplantation	K. Baxby and R. W. G. Johnson	810
Measurement of cell production rates in human gastro-intestinal cancer: a guide to treatment	D. C. Britton, G. Bone, N. A. Wright and R. S. Camplejohn	813

Short papers

Serum α-1-acid glycoprotein as an index of dissemination in breast cancer	J. G. Roberts, J. W. Keyser and M. Baum	816
The immune reaction to human breast cancer: a comparison of skin and leucocyte migration tests	M. Maureen Roberts and Eleanor M. Bathgate	820
A controlled clinical trial of three methods of closure of laparotomy wounds	J. C. Goligher, T. T. Irvin, D. Johnston, F. T. de Dombal, G. L. Hill and J. C. Horrocks	823
Is a 'second look operation' justified in suspected recurrences after abdominal cancer surgery?	Harold Ellis	830
The internal sphincter and Lord's procedure for haemorrhoids	B. D. Hancock and K. Smith	833
Prolonged symptomatic and radiological remission of colonic gas cysts after oxygen therapy	A. P. Wyatt	837
The place of frozen section in the practical management of melanoma	L. E. Hughes	840
The importance of an innervated and intact antrum and pylorus in preventing postoperative duodenogastric reflux and gastritis	M. R. B. Keighley, P. Asquith, J. A. C. Edwards and J. Alexander-Williams	845
Controlled clinical trial comparing early with interval cholecystectomy for acute cholecystitis	P. McArthur, A. Cuschieri, R. A. Sells and R. Shields	850

Number 11

Review paper

		Page
The role of surgery in the management of Hodgkin's disease	Miles Irving	853

Original papers

Measurement of the immune response to an allograft: amino acid incorporation by peripheral white blood cells in man	R. W. Blamey, R. C. Bennett, A. M. Singer, Rita Nicol and J. Harrison	863
Experimental studies on the pathophysiological responses of the newborn to injury	R. A. Little	868
Recurrence of gastric ulcer after selective vagotomy and pyloroplasty for chronic uncomplicated gastric ulcer: a 5–10-year follow-up	Jacinto de Miguel	875
The effect of the size of the gastric outlet on gastric emptying after vagotomy for duodenal ulcer	W. D. George, D. J. Cowley, C. M. Royston, H. I. Glass and J. Spencer	879
Bleeding Meckel's diverticulum diagnosed by mesenteric arteriography	T. J. Hall	882
Intrabiliary rupture of hydatid cyst of the liver	Y. B. Kattan	885
A rare complication of hydrocele	A. C. Chatterjee	891
Experience with 26 reservoir ileostomies	J. C. Goligher and D. Lintott	893
The complications of synchronous combined excission for adenocarcinoma of the rectum at St Mark's Hospital	C. G. Marks and Jean K. Ritchie	901
An assessment of the value of the white cell count in the management of suspected acute appendicitis	J. P. Bolton, E. R. Craven, R. J. Croft and N. Menzies-Gow	906
Comparison of impedance and strain gauge plethysmography in the measurement of blood flow in the lower limb	I. G. Schraibman, D. Mott, G. P. Naylor and D. Charlesworth	909
The surgical cure of primary varicose veins	Stanley Rivlin	913
Bilateral simultaneous rupture of the quadriceps tendons	B. J. Brotherton and J. Ball	918
Loose bodies in the elbow	M. S. Bell	921
Reviews and notices of books		925

Number 12

Original papers

Surgical complications of implanting pacemakers	Harold Siddons and K. Nowak	929
The efficiency of surgical masks of varying design and composition	Louis B. Quesnel	936
Identification of talc on surgeons' gloves and in tissue from starch granulomas	W. J. Henderson, C. Melville-Jones, W. T. Barr and K. Griffiths	941
The effect of metal clips on the tensile properties of healing skin wounds	I. D. Harrison, D. F. Williams and A. Cuschieri	945
How tight should tension sutures be tied? A controlled clinical trial	I. L. Rosenberg, T. G. Brennan and G. R. Giles	950
Does the choice of suture material affect the incidence of wound infection?	G. L. Mouzas and A. Yeadon	952
Gangrene of the tongue following self-application of a rubber band	T. Dutta and K. Vasudevan	956
In situ intraduct carcinoma of the breast: a long term follow-up study	R. R. Millis and G. S. J. Thynne	957
The survival rate of men with carcinoma of the breast	R. W. T. Slack	963
Operative cholangiography: a reappraisal based on a review of 400 cholangiograms	Irvin Faris, James P. S. Thomson, D. J. Grundy and L. P. Le Quesne	966

- *Safe central venous nutrition. Guidelines for prevention and management of complications* (M. H. Parsa, J. M. Ferrer and D. V. Habif), 502

Reviews (Titles), *continued*
Scientific foundations of surgery (ed. C. Wells, J. Kyle and J. E. Dunphy), 335
Sémiologie chirurgicale (L. Léger), 671
Soviet research in pharmacology and toxicology (W. H. Fitzpatrick), 672
Spinal deformity in neurological and muscular disorders (ed. J. H. Hardy), 926
The spleen (A. I. S. Macpherson, J. Richmond and A. E. Stuart), 166
Stress fractures (M. Devas), 988
Stroke. Diagnosis and management. Current procedures and equipment (ed. W. S. Fields and J. Moossy), 168
The structure and biochemistry of cartilage (A. Serafini-Fracassini and J. W. Smith), 168
Surgery (R. M. Kirk, J. Maynard and A. N. Henry), 334
1972 *Surgery annual. Volume* 4 (ed. P. Cooper and L. M. Nyhus), 83
Surgery annual: 1974 *Vol. VI* (ed. L. M. Nyhus), 755
The surgery of the central nervous system (D. W. C. Northfield), 82
Surgery of the gastrointestinal tract (ed. J. S. Najarian and J. P. Delaney), 250
Surgery of the liver and portal circulation (W. V. McDermott), 334
Surgery of the lung. The Coventry conference (ed. R. E. Smith and W. G. Williams), 252
Surgical aspects of haemodialysis (P. R. F. Bell and K. C. Calman), 584
Surgical forum—the liver (ed. R. Smith), 754
Surgical pathology (L. V. Ackerman and J. Rosai), 418
Surgical technology. Basis for clinical practice (M. L. Hoeller), 585
Surgical treatment of facial injuries (V. H. Kazanjian and J. M. Converse), 418
Surgical treatment of head and neck tumours (ed. J. F. Barbosa), 503
Symposium on management of cleft lip and palate and associated deformities. Volume 8 (ed. N. G. Georgiade), 756
Symposium on reconstructive hand surgery. Volume 9 (ed. J. W. Littler, L. M. Cramer and J. W. Smith), 588
A synopsis of anaesthesia (J. A. Lee and R. S. Atkinson), 166
The systematic manifestations of inflammatory bowel disease (ed. W. M. Lukash and R. B. Johnson), 755
A textbook of surgery (ed. Mahadevan), 670
Therapeutic aspects of nutrition (ed. J. H. P. Jonxis, H. K. A. Visser and J. A. Troelstra), 80
Transfusion of blood preserved by freezing (S. Sumida), 415
Trauma management (E. F. Cave, J. F. Burke and R. J. Boyd), 671
The treatment of breast cancer (ed. Sir Hedley Atkins), 416
The treatment of chronic pain (ed. F. D. Hart), 167
The treatment of prostatic hypertrophy and neoplasia (ed. J. E. Castro), 420
Tumour surgery of the head and neck (R. S. Pollack), 925
Tumours of the esophagus and stomach (S-C. Ming), 503
Tumours of the extra-adrenal paraganglion system (including chemoreceptors) (G. G. Glenner and P. M. Grimley), 82
Tumours of the major salivary glands (atlas of tumour pathology, second series) (A. C. Thackray and R. B. Lucas), 671
Tumours of the male genital system (F. K. Mostofi and E. B. Price), 165
Urology and renal medicine (J. E. Newsam and J. J. B. Petrie), 925
Vagotomy. Latest advances (ed. F. Holle and S. Andersson), 926
Vascular malformations (angiodysplasia) (ed. E. Malan), 417

Reviews (Titles), *continued*
Vascular surgery. Volume I. Peripheral arterial diseases (J. J. Cranley), 584
Ventilatory and phonatory control systems (ed. B. Wyke), 755
1974 *Year book of plastic and reconstructive surgery* (ed. K. L. Stephenson et al.), 419
1974 *Year book of surgery* (ed. S. I. Schwartz et al.), 753

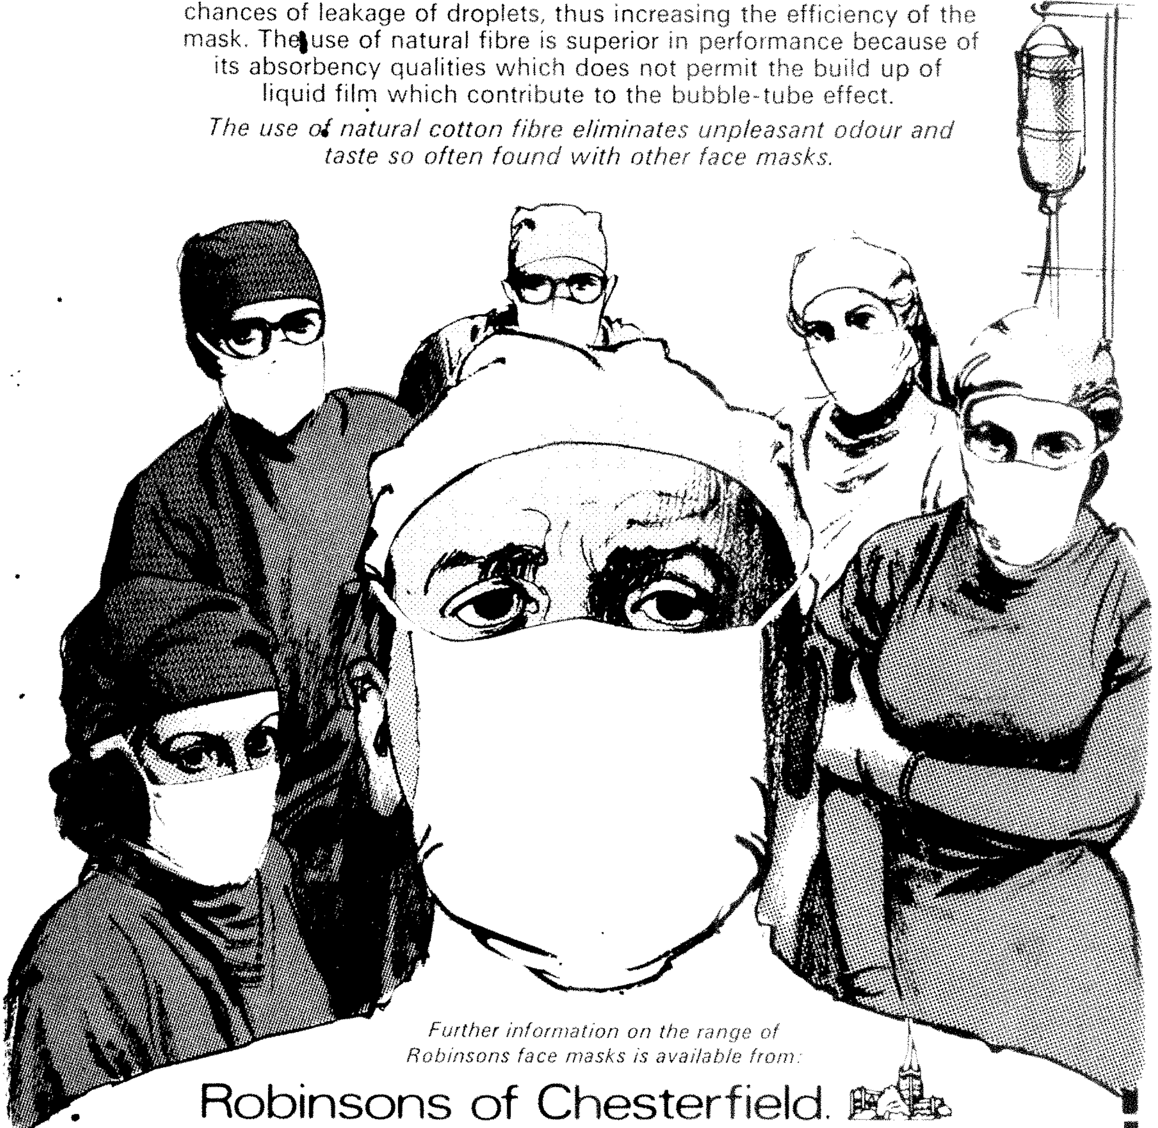
The facts behind the mask

The Cestra mask has high absorbency qualities and high filtration efficiency. Made from cotton fibre, it is soft and extends well back over the cheeks and under the chin, covering a larger area than many other masks. The extensive facial coverage decreases the chances of leakage of droplets, thus increasing the efficiency of the mask. The use of natural fibre is superior in performance because of its absorbency qualities which does not permit the build up of liquid film which contribute to the bubble-tube effect.

The use of natural cotton fibre eliminates unpleasant odour and taste so often found with other face masks.



Further information on the range of Robinsons face masks is available from:

Robinsons of Chesterfield.

Robinson & Sons Limited, Wheat Bridge, Chesterfield S40 2AD.

CHARLES C THOMAS • PUBLISHER

CURRENT MANAGEMENT OF TRAUMA IN SURGERY AND GENERAL PRACTICE *edited by* **Teruo Matsumoto**, *The Hahnemann Medical College and Hospital of Philadelphia, Philadelphia, Pennsylvania. (29 Contributors)* The purpose of this text is to provide comprehensive understanding of the minimum but essential didactic and practical methods of trauma management. It is designed to survey current concepts in the management of various aspects of trauma as well as complications and shock related to these conditions. Particular emphasis is placed on the practical aspects of pathophysiology, new diagnostic techniques and the best approach for the practicing surgeon. *'75, 400 pp. (5 3/8 x 8 1/2), 89 il. $23.50*

CLINICAL APPLICATIONS OF ZINC METABOLISM *edited by* **Walter J. Pories**, *Case Western Reserve Univ., Cleveland, Ohio;* **William H. Strain**, *Cleveland Metropolitan General Hospital, Cleveland, Ohio;* **Jeng M. Hsu**, *Johns Hopkins Univ., Baltimore, Maryland; and* **Raymond L. Woosley**, *Meyer Laboratories, Fort Lauderdale, Florida. Foreword by* **Bert L. Vallee.** *(45 Contributors)* Many clinical applications of zinc therapy are detailed in this volume including the critical importance of zinc therapy in the two basic metabolic processes of growth and repair. The nutritional effects of zinc in man and biochemical and metabolic effects of zinc deficiency are discussed. Other topics include the role of zinc in protein synthesis, zinc therapy in surgical patients and in the management of severely burned patients. *'75, 320 pp. (6 3/4 x 9 3/4), 79 il., 80 tables, $28.50*

PROBLEMS OF RECURRENT HERNIA *by* **Robert C. Kimberly**, *Johns Hopkins Medical School, Baltimore, Maryland.* With emphasis on treatment of the patient as well as of the hernia, this book will aid surgeons in managing the problem of recurrent hernia. The causes of the recurrence of a hernia are discussed with stress upon the role of infection and pulmonary complications. Preoperative preparation is among the general principles in the management of recurrent hernia that are considered. Recurrent inguinal, femoral, ventral, diaphragmatic and muscle hernias are discussed separately. The use of prosthetic materials in recurrent hernia is also covered. This volume will help to make difficult operations easy. *'75, 76 pp. (5 3/8 x 8 1/2), 21 il., $6.50, paper*

PATHOLOGY AND SURGERY OF THE SALIVARY GLANDS *by* **Jose Yoel**, *Rawson Hospital, Municipal Post Graduate School of Medicine, Buenos Aires, Argentina. Forewords by* **Pierre Cernea, John Conley, Hector Marino** *and* **S. L. Perzik.** Anatomy, physiology, pathology and semiology, instrumental and radiological exploration, and medical and surgical treatment of salivary gland diseases have been extensively covered in this book. Clear anatomophysiologic sketches and magnificent illustrations of the operative stages clearly depict what the surgeon actually sees in the operative field. Fundamental concepts of embryology, histology, physiology, endocrinology, and general pathology of the salivary glands and their diagnostic methods are reviewed. *'75, 1446 pp. (7 x 10), 2074 il. (7 in full color), 6 tables, $132.50*

NORMAL AND ABNORMAL GROWTH OF THE PROSTATE *edited by* **Martin Goland**, *Southwest Foundation for Research and Education, San Antonio, Texas. (90 Contributors)* This text summarizes current knowledge concerning the prostate gland. It is divided into sections covering such areas as embryology, development and pathology of the prostate gland, metabolism of steroids in prostatic tissue, regulation of prostatic metabolism, ligandmacromolecular binding and transport mechanisms, and experimental and clinical approaches to the prostatic cavity. Some of the chapter topics included in these sections are the fetal and neonatal prostate, androgen dynamics *in vitro* in the human prostate gland, hormonal regulation of RNA synthesis, prolactin and the prostate, and endocrine profiles in carcinoma of the prostate. *'75, 964 pp., 451 il., 123 tables, $48.75*

ANKLE FRACTURES: Treatment Without Casts *by* **Leo K. Cooper**, *Gary, Indiana.* The cases and treatments cited stem from a practice of this treatment with the scope being limited to fractures involving the ankle joint. Various types of fractures which occur in the ankle joint and at times are associated with severe injuries of the foot are represented along with treatment, physiology, complications and case studies. The author wishes to stress the importance of early, rapid, accurate fixation of fractures of the ankle and rapid restoration of the physiology of the extremity. This is characterized by early motion of the muscles and joints which in turn improve the circulation and promote rapid healing. *'74, 124 pp. (8 1/2 x 11), 172 il., $18.50*

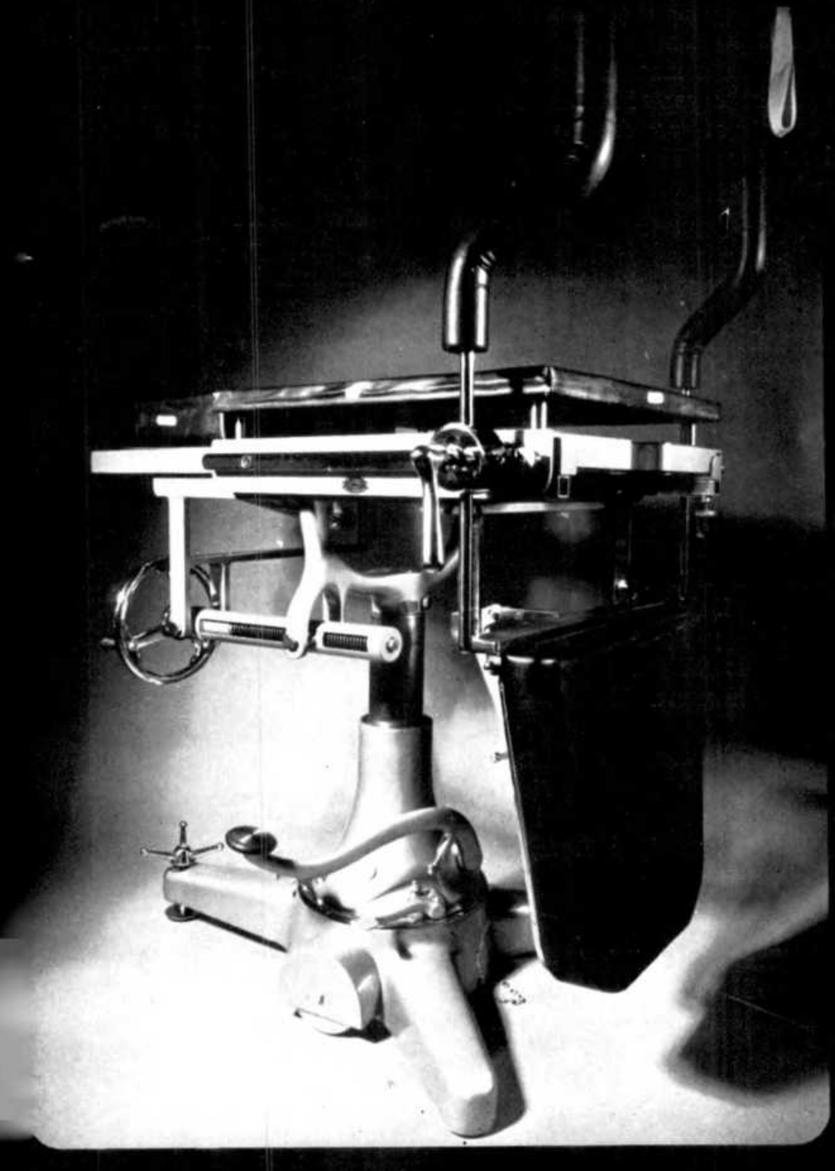
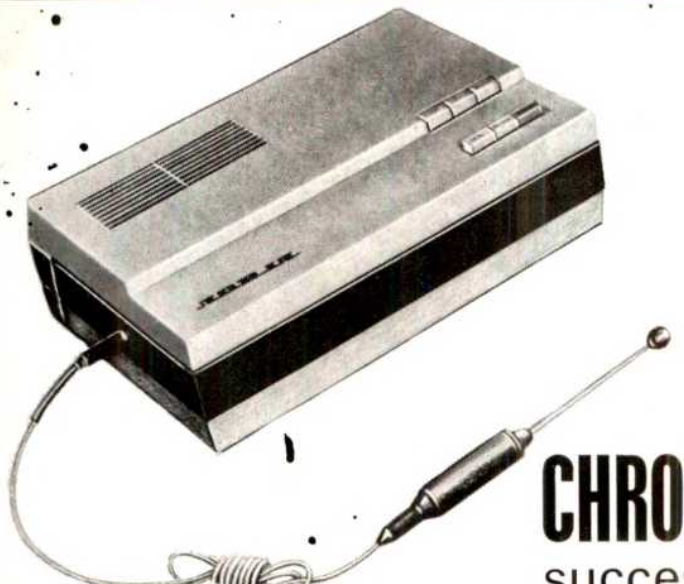
THACKRAY



Belfast table

A table for perineal and general surgery which is designed to allow the patient to be placed in lithotomy position without being lifted or pulled down the table.

ackray Limited, Head Office: P.O. Box 171 Park Street, Leeds LS1 1RQ



The LOR-1A
APPARATUS

CHRONIC TONSILLITIS
successfully treated by
ultrasonic therapy

The LOR-1A apparatus produces mechanical vibrations of ultrasonic frequency which have a therapeutic effect on infected tonsils. Clinical tests have shown 75% success in patients treated. Advantages of the LOR-1A are its small dimensions and low weight (less than 5 kg) and its proven safety, reliability and ease of operation. Small ultrasonic generator of low operating voltage permits direct treatment to tonsils.

BURNS including Thermal Injury

The Journal of the International Society for Burn Injuries

Editor, J. E. LAING, FRCS

To counter the high mortality and morbidity caused by burn injuries needs the teamwork of a wide range of specialists: treatment of the patient can involve plastic, paediatric and orthopaedic surgeons, biologists, immunologists and bacteriologists, while the rehabilitation of the patient can need the efforts of occupational therapists, physiotherapists, psychiatrists and social workers. This new journal is published to foster the exchange of information amongst all those engaged in preventing and minimizing the effects of burn injuries. BURNS is sponsored by the International Society for Burn Injuries, whose aims are to transcend national boundaries in improving the prevention and care of burns by education, research, practical advice and assistance, and the encouragement of cooperation between all countries and all specialists.

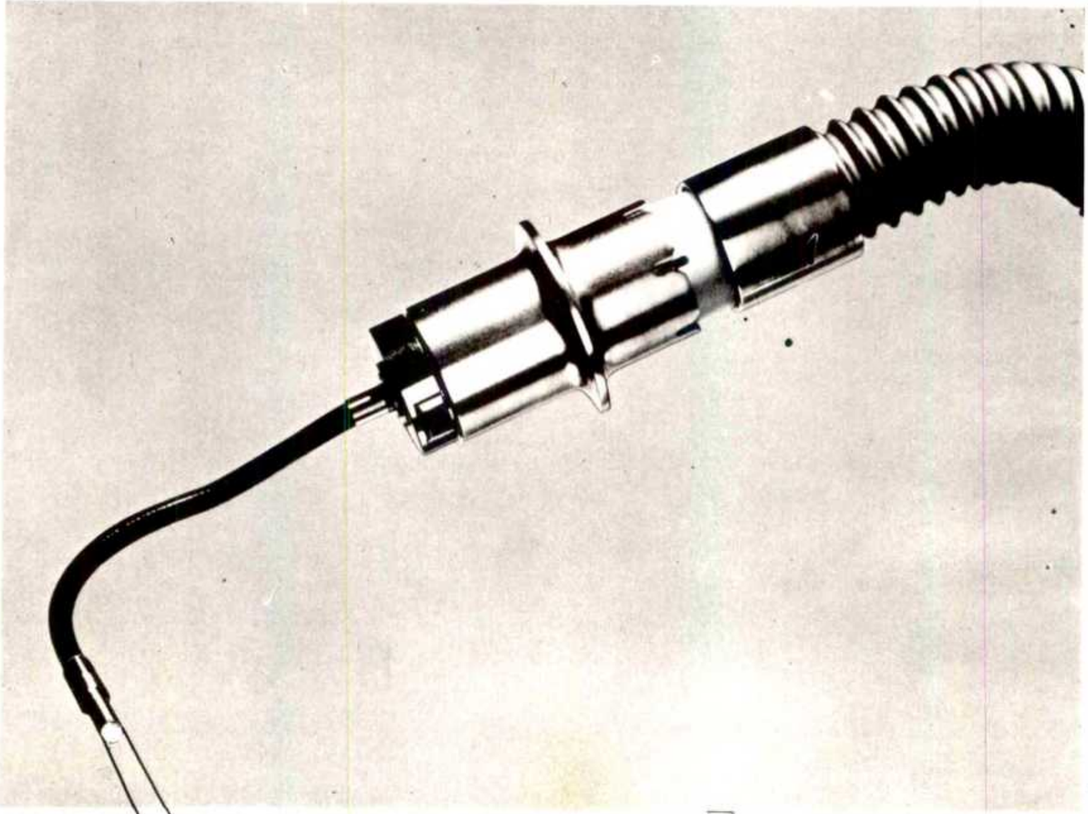
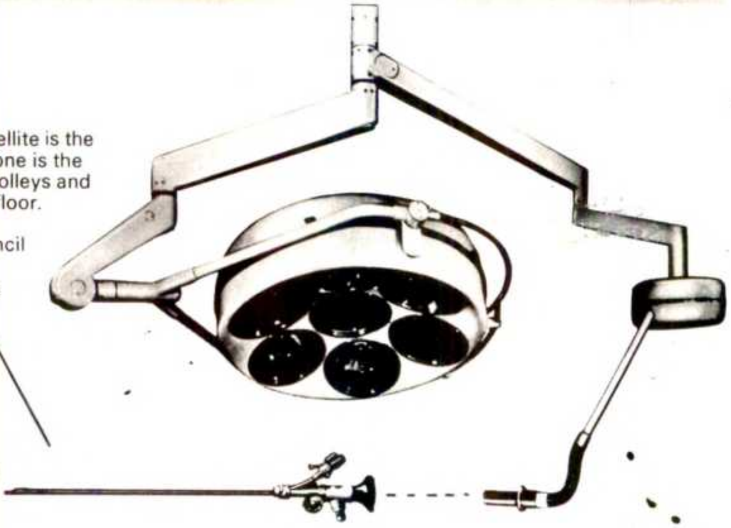
FLEXIBLE PENCIL LIGHT





The Boston lamp with its GFO Satellite is the ideal endoscopic light source. Gone is the need for a separate source, for trolleys and mains cables trailing across the floor.

Illustrated above is a flexible pencil light, ideal for Neuro and ENT surgery, shown connected to the GFO Satellite.

Most glass-fibre endoscopic instruments can be connected in this way.

Operational Flexibility

The dual channel ACM F9A and F9R are the world's most advanced operating coloscopes. With either, a surgeon has at his fingertips a range of capabilities and techniques.

The F9A has a useful length of 165 cm., sufficient for a variety of therapeutic procedures up to the caecum, while the shorter (105 cm.) F9R, with a softer shaft, can cover most of the known pathology of the colon.

Even the most delicate and precise procedures become routine with the F9A and F9R. Both models feature ACM's unique twin channel design (7 Fr. and 12 Fr.), each with independent suction, which permits the surgeon to select any combination of snares, forceps, electrodes, retrievers, cytology brushes etc., that he needs.

And of course, both incorporate all the advanced features of other ACM endoscopes, including :–

- *Polydirectional distal tip with 320° deflection and single-lever control
- *Separate channel for air, CO_2 or water
- *Wide angle, fixed focus optics
- *Clear, bright circular image with 12X magnification

The F9A and F9R are supported by a full range of accessories and will accept the unique ACM teaching attachment. There are single channel models too, the ACM F9S and F9L, for diagnosis and less demanding surgica procedures.

For further details of the ACM F9 range, the world's most versatile coloscopes, please telephone or write to us.

Our experience is something you can rely on

Remploy's contribution to Orthotics goes far beyond providing a comprehensive range of orthopaedic equipment.

Remploy are able to offer a unique measuring and fitting service for all their appliances and footwear, and have produced two orthopaedic brochures which are an invaluable aid to work in this field. Rely on this experience and send for literature, now.

Remploy

An exceptional name in Orthotics

A.H. Knight Remploy Limited (Orthopaedic Division),
Remploy House, 415 Edgware Road, Cricklewood,
London NW2 6LR. Telephone: 01-452 8020.

FIGHT BACK AGAINST CANCER

It is good to remember that most people live their lives untouched by any form of cancer.

But as all too many are aware, cancer is something that casts its shadow far beyond those it directly affects. That is why so many people think it right to help the urgent work of the Imperial Cancer Research Fund.

From our discoveries in the past has come much of today's hope for sufferers. To go forward with our research for future alleviation, we ask *your* help in the present.

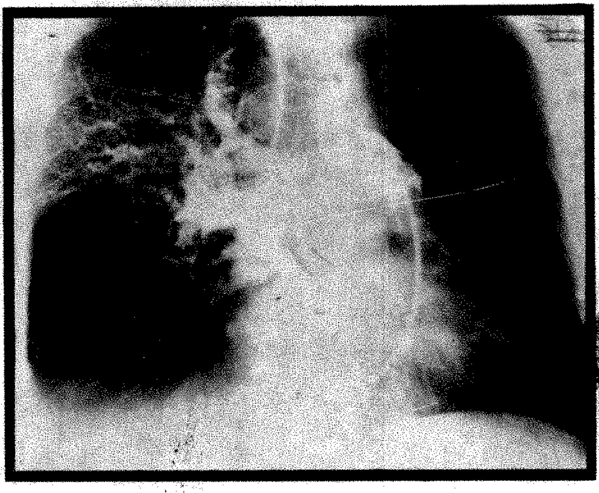
IMPERIAL CANCER RESEARCH FUND

Donations will be most gratefully received by the Appeals Secretary,
Room 164/4, P.O. Box 123, Lincoln's Inn Fields, London WC2A 3PX

RED ALERT!



When acute massive pulmonary embolism occurs put them on Kabikinase to dissolve the embolus and the still threatening deep vein thrombus and restore the flow. (Lysis achieved, anticoagulate with heparin to prevent rethrombosis.)

"We believe that the current treatment of choice for most cases of acute life-threatening pulmonary embolism is streptokinase." 1

1 Comparison by Controlled Clinical Trial of Streptokinase and Heparin in Treatment of Life-threatening Pulmonary Embolism. Brit. med. J. **1.** 343 (1974).

KABIKINASE

(pure streptokinase)

Full information, brochure and wall card on request.

Kabikinase is manufactured by AB Kabi, Stockholm, Sweden, and is available only from:

KabiVitrum

KabiVitrum Limited,
Bilton House,
Uxbridge Road,
London W5 2TH
